11 **ABSTRACT**

12 The crystal structure of the rare, spinel-related Sb mineral filipstadite from Långban,  
13 Filipstad district, Värmland, Sweden, has been solved and refined in the space group  $Fd\bar{3}m$   
14 [ $a = 25.9300(6)$  Å,  $V = 17434.4(5)$  Å<sup>3</sup>,  $Z = 216$ ] and refined to  $R = 4.41\%$  for  $681 F_o > 4\sigma(F_o)$   
15 using MoK $\alpha$  X-ray data. The structure of filipstadite is topologically identical to the spinel-  
16 type structure with cations occupying 1/8 of the tetrahedral (T) and 1/2 of the octahedral (M)  
17 interstices of a cubic close-packing of oxygen atoms. Due to the cation ordering, which leads  
18 to the tripling of the unit-cell edge, the M and T sites of the spinel-type structure split into six  
19 and five independent sites, respectively. Chemical composition was determined by electron  
20 microprobe. The fractions of major cations obtained from chemical analysis were distributed  
21 between T and M sites taking into account the weighted electron number at both T and M  
22 sites, and minimizing the discrepancy between the calculated and the observed overall <M-  
23 O> distance. Cations present in minor amounts were assigned on the basis of their known site  
24 preference. The obtained populations ( $2M = \text{Mn}^{2+}_{0.56}\text{Mg}_{0.76}\text{Fe}^{3+}_{0.16}\text{Al}_{0.02}\text{Sb}^{5+}_{0.50}$ ;  $T =$   
25  $\text{Mn}^{2+}_{0.60}\text{Mg}_{0.07}\text{Fe}^{3+}_{0.30}\text{Zn}_{0.02}\text{Si}^{4+}_{0.01}$ ) were then tentatively distributed among the individual M  
26 and T sites on the basis of crystal chemical considerations.

29 distribution; Långban (Sweden).

30 INTRODUCTION

31 Filipstadite, ideally  $(\text{Mn}^{2+}, \text{Mg})_2(\text{Fe}^{3+}_{0.5}\text{Sb}^{5+}_{0.5})\text{O}_4$ , was first described by Dunn et al.  
32 (1988) as a new spinel-related mineral having orthorhombic symmetry and unit cell  
33 parameters  $a = 36.7$ ,  $b = 36.7$ ,  $c = 25.9$  Å. Using Weissenberg and precession methods, Dunn  
34 et al. showed a substructure-superstructure relationship with intense reflections corresponding  
35 to those of spinel-type structure ( $a = 3\sqrt{2}a_s$ ,  $b = 3\sqrt{2}a_s$  and  $c = 3a_s$ , where  $a_s$  is the unit-cell  
36 translation of a spinel-type structure) and supposed the superstructure to be due to cation  
37 ordering at the octahedral sites. This reasonable hypothesis, however, remained to be proved  
38 by a structure analysis.

39 At the type-locality (Långban, Filipstad district, Värmland, Sweden) filipstadite occurs  
40 intimately associated with jacobsite, ingersonite and calcite. In particular, filipstadite was  
41 described to replace jacobsite,  $(\text{Mn}^{2+}, \text{Fe}^{2+}, \text{Mg})(\text{Fe}^{3+}, \text{Mn}^{3+})_2\text{O}_4$ , and many filipstadite crystals  
42 were reported as having residual, irregular cores of jacobsite. Two other occurrences of  
43 filipstadite were later reported at two other 'Långban-type' Mn-Fe deposits, namely  
44 Jakobsberg and Nordmark, in south-central Sweden (Holtstam 1993; Holtstam et al. 1998). At  
45 Jakobsberg the mineral coexists with hausmannite, calcite, forsterite, phlogopite and another  
46 spinel-related phase exhibiting close similarities with filipstadite (Holtstam 1993) which was  
47 later approved as a new mineral species with the name tegengrenite (Holtstam and Larsson  
48 2000). At Nordmark filipstadite occurs in fine-grained rock samples, including arsenates of  
49 svabite-johnbaumite and adelite-tilasite series, forsterite, phlogopite, manganoan calcite,  
50 plumbian stibarsen and plumbian romeite (Holtstam et al. 1998). Interestingly, in the  
51 Nordmark samples described by Holtstam et al. (1998), Sb-poor filipstadite and Sb-rich  
52 jacobsite occur, possibly indicating solid solution between jacobsite-magnesioferrite spinel

53 and filipstadite. As pointed out by these authors, however, the crystallographic features of  
54 filipstadite involving lower symmetry and superstructure should inhibit complete solid  
55 solution and some intermediate composition might reasonably represent disordered  
56 metastable phases and/or sub-optical topotactic intergrowths.

57 Much attention has been devoted to the cation distribution in spinel-type oxides in the  
58 last decades (Lavina et al. 2002 and references therein), but only few crystal-chemical  
59 relationships are known for spinels containing  $\text{Sb}^{5+}$  or other pentavalent cations. According to  
60 Tarte and Rulmont (1988), the cation distribution over tetrahedral and octahedral sites in  
61 spinels containing high-valence cations is found to be in contradiction with the well known  
62 relative site preferences, which are based on their size and/or, in the case of cations subjected  
63 to Jahn-Teller distortion, on their crystal field stabilization energies.

64 To contribute to the scientific debate on the spinel crystal chemistry, we present the  
65 crystal structure determination of filipstadite from the type material (sample 163012,  
66 Smithsonian Institution, Washington, U.S.A.). Crystal chemical considerations led us to  
67 propose a tentative distribution of cations among octahedral and tetrahedral sites.

68

## 69 EXPERIMENTAL METHODS

### 70 **X-ray diffraction**

71 A crystal was selected and preliminarily examined with a Bruker P4 single-crystal  
72 diffractometer using graphite-monochromatized  $\text{MoK}\alpha$  radiation. The intensity data collection  
73 was done with an Oxford Diffraction Xcalibur 3 diffractometer, fitted with a Sapphire 2 CCD  
74 detector (see Table 1 for details). Intensity integration and standard Lorentz-polarization  
75 corrections were performed with the *CrysAlis* RED (Oxford Diffraction 2006) software  
76 package. The program ABSPACK in *CrysAlis* RED (Oxford Diffraction 2006) was used for  
77 the absorption correction. A total of 1754 frames of data were collected at room temperature

78 (2 $\theta$  MoK $\alpha$  < 64.60°) with an exposure time of 45 s per frame and a frame width of 0.90. All  
79 the 26652 reflections collected (1459 unique) yielded the cubic supercell:  $a = 25.9300(6)$  Å,  $V$   
80  $= 17434.4(5)$  Å<sup>3</sup>,  $Z = 216$  ( $a = 3a_s$ , with  $a_s$  = translation unit of a cubic spinel-type cell = 8.643  
81 Å). No evidence of split of the superstructure reflections at high-theta angles was observed,  
82 thus suggesting no mixture with significant amounts of jacobsite [ $a = 8.4956(3)$  Å, Lucchesi  
83 et al. 1997;  $a = 8.3413(7)$  Å; Kim et al. 2009].

84

### 85 **Electron microprobe analysis**

86 The crystal used for the structural study was embedded in resin and polished for the  
87 chemical analysis that was performed using a CAMECA-CAMEBAX electron microprobe  
88 operating with a fine-focused beam (~ 1  $\mu$ m) at an acceleration voltage of 20 kV and a beam  
89 current of 20 nA in wavelength-dispersive mode (WDS), with 10 s counting times for peak  
90 and 5 s for total background. X-ray counts were converted in oxide weight percentages using  
91 the PAP correction program supplied by CAMECA (Pouchou and Pichoir 1985). Standard,  
92 WDS line, analyzer crystal, and analytical uncertainty (wt%) for each element were the  
93 following: Mg (MgO, MgK $\alpha$ , TAP analyzer, 0.03); Al (Al<sub>2</sub>O<sub>3</sub>, AlK $\alpha$ , TAP analyzer, 0.04); Si  
94 (diopside, SiK $\alpha$ , TAP analyzer, 0.03); Mn (MnTiO<sub>3</sub>, MnK $\alpha$ , LIF analyzer, 0.07); Fe (Fe<sub>2</sub>O<sub>3</sub>,  
95 FeK $\alpha$ , LIF analyzer, 0.11); Zn (ZnS, ZnK $\alpha$ , LIF analyzer, 0.10); Sb (synthetic Sb<sub>2</sub>S<sub>3</sub>, SbL $\alpha$ ,  
96 PET analyzer, 0.10). The crystal was found to be homogeneous without any inclusion of  
97 jacobsite.

98 Chemical formulae were calculated on the basis of four oxygen atoms and assuming  
99 that Mn and Fe are present at the divalent and trivalent state, respectively (Table 2). Sums of  
100 cations ranging from 2.996 to 3.010 apfu confirmed the above assumption.

101

102

STRUCTURE SOLUTION

103 The systematic absences in the whole intensity data set were consistent with the space  
104 group  $Fd\bar{3}m$ . Reflections were merged accordingly ( $R_{\text{int}} = 4.40\%$ ). The positions of metal  
105 atoms were found using the Patterson interpretation of the SHELXS-97 package (Sheldrick  
106 2008); successive  $F_o$ -Fourier syntheses allowed us to locate all the O atoms yielding the  
107 expected unit-cell content. Full occupancy was assumed for all sites. Site-scattering values  
108 were refined for all cations using ionized atomic scattering factors as follows:  $\text{Fe}^{3+}$  vs.  $\text{Mg}^{2+}$   
109 (T sites),  $\text{Sb}^{5+}$  vs.  $\text{Mg}^{2+}$  (M sites). The M1 octahedron resulted to be occupied by  $\text{Sb}^{5+}$  only  
110 and its occupancy was fixed accordingly. Both scattering curves and  $\Delta f'$ ,  $\Delta f''$  coefficients were  
111 taken from the *International Tables for X-ray Crystallography*, volume C (Wilson and Prince  
112 1999). Anisotropic refinements by full-matrix least-squares on 110 refined parameters led to a  
113 final discrepancy factor of 4.41% for 681 observed reflections [ $F_o > 4\sigma(F_o)$ ] and 6.40% for all  
114 unique 1459 data.

115 The mean electron numbers at the cation sites together with the atomic coordinates are  
116 reported in Table 3. Anisotropic displacement parameters are reported in Table 4. Table 5<sup>1</sup>  
117 lists the observed and calculated structure factors.

118

119

## RESULTS

120 In keeping with the weakness of the superstructure reflections, the structure of  
121 filipstadite is topologically identical to the spinel-type structure with cations occupying 1/8 of  
122 the tetrahedral (T) and 1/2 of the octahedral (M) interstices of a cubic close-packing of  
123 oxygen atoms. Due to the cation ordering, the M and T sites of the spinel-type structure split  
124 into six and five independent sites, respectively. The structure of filipstadite, like that of  
125 common spinels, can be described as a sequence of pairs of polyhedral layers (hereafter

---

<sup>1</sup> For a copy of Table 5, document item AMxxxxx, contact the Business Office of the Mineralogical Society of America (see inside front cover of recent issue) for price information. Deposit items may also be available on the American Mineralogist web site at <http://www.minsocam.org>.

126 named X and Y) stacked along [111]. As far as the cation sites are concerned, X and Y layers  
127 have general formula  $M_3$  and  $MT_2$  respectively. As each layer is projected along [111],  
128 successive pairs of X-Y layers appear to be displaced  $\frac{1}{4}$   $[11\bar{2}]$  with respect to each other.  
129 Thus, in the unit cell of spinels three identical XY pairs succeed along [111]. In filipstadite,  
130 the ordering of cations determines two types of  $M_3$  layers, X and X' (Fig.1, top), and two  
131 types of  $MT_2$  layers, Y and Y' (Fig. 1, bottom). The repeat unit, consisting of six polyhedral  
132 layers, namely X-Y-X'-Y'-X'-Y, is thus three times the XY unit of a basic spinel structure.

133 Taking into account the different multiplicity of both octahedral and tetrahedral cations  
134 (Table 3), the total electron number ( $e^-_T + 2e^-_M = 25.0 + 53.6 = 78.6$ ) is in satisfactory accord  
135 with that (77.3) calculated on the basis of the chemical formula derived by microprobe data,  
136  $Mn^{2+}_{1.16}Mg_{0.83}Sb^{5+}_{0.50}Fe^{3+}_{0.48}Zn_{0.02}Al_{0.02}Si^{4+}_{0.01}O_4$ . Bond distances and distortion parameters  
137 are reported in Table 6. All tetrahedra are rather regular and exhibit a small range of variation  
138 of the mean electron number (24.5 – 25.2), while the same value for the octahedral sites is  
139 very scattered (16.9 - 51.0). The overall average bond distances, weighted taking into account  
140 the different multiplicities of the individual sites, are 2.076 Å and 2.029 Å for octahedra and  
141 tetrahedra, respectively.

142

#### 143 DISCUSSION

144 A site assignment in the structure of filipstadite is not straightforward and requires some  
145 reasonable simplifications. Minor cations were assigned to one site on the basis of their  
146 general site preference: in particular,  $Si^{4+}$  (Urusov 1983) and Zn (Navrotsky and Kleppa  
147 1967) were assigned to the T site, and  $Al^{3+}$  (Urusov 1983) to the M site. Since electrons in M  
148 sites range from 16.9 up to 51.0, and in keeping with the literature on complex spinel-like  
149 antimonates (Tarte and Preudhomme 1979; Preudhomme et al. 1980; Tarte and Rulmont  
150 1988), all  $Sb^{5+}$  was assigned to the M sites. On the other hand, the other main cations, i.e.

151  $\text{Mn}^{2+}$ ,  $\text{Fe}^{3+}$  and Mg, may occupy both the octahedral and the tetrahedral sites. Due to the fact  
152 that the relative preference for tetrahedral sites in spinels increases from  $\text{Fe}^{3+}$  and Mg towards  
153  $\text{Mn}^{2+}$  (Hastings and Corliss 1956; Buessem and Butler 1963; Navrotsky and Kleppa 1967;  
154 Sawatzky et al. 1967; Morrish and Clark 1975; Lucchesi et al. 1997), one could be tempted to  
155 fill the T sites mainly with  $\text{Mn}^{2+}$  allowing all  $\text{Fe}^{3+}$  and Mg to occupy the M sites. The  
156 consequent assignment of all  $\text{Fe}^{3+}$  in the octahedra, indeed, would be in substantial accord  
157 with what observed in natural jacobsite, where  $\text{Fe}^{3+}$ , according to the Mössbauer study carried  
158 out by Maia et al. (1993), is ordered at the octahedral site. To evaluate the reliability of such a  
159 hypothesis,  $\langle\text{M-O}\rangle$  distance was calculated with the remaining cations ( $2\text{M} =$   
160  $\text{Mg}_{0.83}\text{Mn}^{2+}_{0.19}\text{Fe}^{3+}_{0.46}\text{Al}_{0.02}\text{Sb}^{5+}_{0.50}$ ) on the basis of pure  $\langle\text{M-O}\rangle$  reference bond lengths (Table  
161 7) and assuming a linear contribution of each cation. The value obtained (2.046 Å), markedly  
162 shorter than experimental one (2.076 Å), indicates that higher amounts of  $\text{Mn}^{2+}$ , the largest  
163 cation in filipstadite, enters the M sites and a mixing of  $\text{Fe}^{3+}$  and Mg enters the T sites. On the  
164 other hand, if all  $\text{Fe}^{3+}$  is located at the T sites together with Si and Zn and an appropriate  
165 mixing of  $\text{Mn}^{2+}$  and Mg to maintain the mean electron number close to 25, the  $\langle\text{M-O}\rangle$   
166 distance calculated with the remaining cations ( $2\text{M} = \text{Mg}_{0.80}\text{Mn}^{2+}_{0.68}\text{Al}_{0.02}\text{Sb}^{5+}_{0.50}$ ) results even  
167 too long (2.087 Å) with respect to the observed mean value (2.076 Å), thus suggesting a more  
168 complex ordering model with  $\text{Fe}^{3+}$  entering both tetrahedral and octahedral cavities. Between  
169 the two arbitrary models described above, however, the second one leads to a minor  
170 discrepancy between the calculated and the observed value, indicating that  $\text{Fe}^{3+}$  is mainly  
171 located to tetrahedral sites; as a consequence, migration of higher than expected amounts of  
172  $\text{Mn}^{2+}$  from tetrahedral into octahedral sites occurs, probably to balance the effects of the  
173 incorporation of the high-charged cation ( $\text{Sb}^{5+}$ ) at the octahedra. Indeed, according to Tarte  
174 and Rulmont (1988), in spinel-like compounds containing “high valency cations” abnormal

175 cation distribution are observed which are unexpected on the basis of the well known  
176 preferences of cations for T and M sites.

177 In order to pursue a distribution of cations between T and M sites, the cation fractions  
178 obtained from chemical analysis were assigned taking into account the weighted electron  
179 number at both T and M sites, and minimizing the discrepancy between the calculated and the  
180 observed overall <M-O> distance. The overall <T-O> distance was not used as a constraint  
181 due to the well known differing of tetrahedral bond distances of the same cation as a function  
182 of the octahedral population (Lucchesi et al. 1998, 1999). On the contrary, it is known that  
183 tetrahedral cations show no or very minor influence on the octahedral M-O distances (Lavina  
184 et al. 2002). The following cation populations were obtained:  $2M = 0.56 \text{ Mn}^{2+} + 0.76 \text{ Mg} +$   
185  $0.16 \text{ Fe}^{3+} + 0.02 \text{ Al} + 0.50 \text{ Sb}^{5+}$  ( $\langle n.e \rangle = 53.0$ ;  $\langle \text{M-O} \rangle_{\text{calc}} = 2.075 \text{ \AA}$ );  $T = 0.60 \text{ Mn}^{2+} +$   
186  $0.30 \text{ Fe}^{3+} + 0.07 \text{ Mg} + 0.02 \text{ Zn} + 0.01 \text{ Si}$  ( $\langle n.e \rangle = 24.4$ ;  $\langle \text{T-O} \rangle_{\text{calc}} = 1.978 \text{ \AA}$ ). As expected,  
187 for the tetrahedral distance the accord between observed and calculated values is not good; the  
188 calculated <T-O> distance remains too short (1.985 Å) even if a longer reference bond length  
189 for  $^{\text{IV}}\text{Mn}^{2+}\text{-O}$  (2.050 Å) is used as found by Hålenius et al. (2011) in the crystal structure of  
190 fully ordered galaxite ( $\text{MnAl}_2\text{O}_4$ ). It must be taken into consideration, however, that the  
191 unusual presence of high-charged cations in the octahedra likely involves an overall  
192 lengthening of the tetrahedral distances. In this model,  $\text{Fe}^{3+}$  is disordered over tetrahedral and  
193 octahedral sites in a abundance ratio quite similar to that observed in the orthorhombic  
194  $\text{M}^{2+}_4\text{Fe}^{3+}\text{SbO}_8$  spinel-like compounds ( $\text{M}^{2+} = \text{Mg}_{3/4}\text{Zn}_{1/4}$ , Co,  $\text{Co}_{3/4}\text{Ni}_{1/4}$ ,  $\text{Ni}_{3/4}\text{Zn}_{1/4}$ ) where  $\text{Fe}^{3+}$  was  
195 proved to enter both T and M sites, in the 2:1 abundance ratio (Tarte and Preudhomme 1979).

196 Assuming as reliable the obtained partition between T and M sites, an attempt to assign  
197 cations among the individual sites was done as follows. In Figure 2, the <M-O> distances are  
198 plotted against the refined electron number together with data for pure reference bond lengths  
199 taken from literature (black circles) and, for a comparison, the sum of ionic radii of six-

200 coordinated cations and oxygen anions (empty triangles). Points fall along a line between M1  
201 (the smallest octahedron occupied by Sb alone) and M4, the largest (2.117 Å) octahedron  
202 dominated by Mg ( $n.e^- = 16.9$ ). Its position on the plot falls on the Mg-Mn<sup>2+</sup> join, suggesting  
203 incorporation of only Mn<sup>2+</sup> replacing for Mg. After the M4 assignment, the remaining  
204 octahedral cations (i.e., 0.48 Mg + 0.40 Mn<sup>2+</sup> + 0.16 Fe<sup>3+</sup> + 0.02 Al) were tentatively  
205 considered as an unique ‘mixed’ ME species (empty square in Fig. 2) having  $\langle n.e^- \rangle = 19.0$   
206 and  $\langle ME-O \rangle_{calc} = 2.111$  Å. Since the data relative to M5, M6, M3, and M2 show an alignment  
207 without significant displacements from the ME-M1 segment, it was made the assumption that  
208 the given above ‘mixed’ ME species replaces Sb<sup>5+</sup> at different degrees without any preference  
209 for different octahedral sites. Thus, a mixed population [ME<sub>x</sub> Sb<sup>5+</sup><sub>1-x</sub>] with  $x = 0.903, 0.781,$   
210  $0.744,$  and  $0.424,$  was assigned to M5, M6, M3 and M2, respectively. To check the reliability  
211 of this hypothesis, we compared the observed  $\langle M-O \rangle$  distances to those calculated on the  
212 basis of the pure  $\langle M-O \rangle$  reference bond lengths (Table 7). The calculated distances match  
213 fairly well the observed values (Fig. 3). The cation populations thus obtained are given in  
214 Table 8.

215 Due to the relative homogeneity in the mean electron number at the tetrahedral sites  
216 (24.5 – 25.2), it is rather difficult to derive a reliable cation distribution of the remaining 0.60  
217 Mn<sup>2+</sup> + 0.30Fe<sup>3+</sup> + 0.07 Mg + 0.02 Zn + 0.01 Si among the five tetrahedral sites on the basis  
218 of the mean distances alone (Fig. 4), being the geometrical features of tetrahedra in spinels  
219 strongly depending on the octahedral cation population, especially in this case, where the  
220 high-charge Sb<sup>5+</sup> cation heavily affects the bond strengths on the oxygen atoms. In the  
221 structure of filipstadite, like in the spinel structure, each oxygen atom adopts a tetrahedral  
222 configuration linking three M cations and one T. In Figure 5 the individual tetrahedral T-O<sub>i</sub>  
223 distances are plotted against the sum of the positive charge in the three M cations linked to  
224 each O<sub>i</sub>. Obviously, the site fully occupied by Sb<sup>5+</sup> (M1) overcharges the linked O5 oxygen

225 atoms; as a consequence, T2-O5 is the longest individual T-O<sub>i</sub> in the structure (2.079 Å)  
226 whereas the O10 oxygen atom, which is bonded to three M4 (occupied by divalent cations  
227 alone) and one T3, links T3 with the shortest individual T-O<sub>i</sub> distance (1.873 Å). The charge  
228 distribution at the octahedral sites surely affects the partition of Fe<sup>3+</sup> and divalent cations  
229 (mainly Mn<sup>2+</sup> and minor amounts of Mg) among the tetrahedra. The smallest and most regular  
230 T3 tetrahedron, located within the Y layer, is surrounded by twelve M4 octahedra (yellow in  
231 Fig. 1: six belonging to the overlying X, three to Y, and three to the underlying X' layer) and  
232 should be assumed as occupied dominantly by Fe<sup>3+</sup> and Si. On the other hand, T2 shows the  
233 longest <T-O> distance (2.068 Å), even longer than the pure <Mn<sup>2+</sup>-O> reference distance  
234 (2.036 Å). To this site, which exhibits a mean electron number slightly higher than 25, the  
235 available Zn was assigned together with Mn<sup>2+</sup>. To the other tetrahedral sites, namely T5  
236 (2.030 Å), T4 (1.992 Å) and T1 (1.989 Å) the remaining Mn<sup>2+</sup>, Mg and Fe<sup>3+</sup> were tentatively  
237 assigned taking into account both the mean bond distances and the electron number (Table 8).  
238 Although the discrepancies between calculated and observed values for tetrahedral bond  
239 distances are rather high and the observed values, as expected, are higher than those  
240 calculated on the basis of pure reference bond lengths (Fig. 6), the bond strength sums on  
241 oxygen atoms calculated using the assigned cation populations are indeed quite satisfactory  
242 (Table 9).

243

#### FIGURE CAPTIONS

- 319 FIGURE 1\_ Polyhedral layers in the structure of filipstadite projected along [111]. Octahedra  
320 are pictured with different colors as a function of the electron number obtained by  
321 occupancy refinement: < 20 = yellow (M4), 20 ÷ 30 = orange (M3, M5, M6); 30 ÷  
322 40 = red (M2); > 40 = dark red (M1). All tetrahedra are in gray. Along [111] the

323 repeat unit consists of six polyhedral layers, namely X-Y-X'-Y'-X'-Y. Successive  
324 slab of six layers are displaced  $\frac{1}{4} [11\bar{2}]$  with respect to each other.

325

326 FIGURE 2\_ The octahedral  $\langle M-O \rangle$  distances plotted against the refined electron number in the  
327 M sites of filipstadite (black squares); black circles refer to data for reference bond  
328 lengths taken from literature (see Table 7) and empty triangles refer to the sum of  
329 ionic radii of six-coordinated cations and oxygen anions. The empty square ( $\langle n.e \rangle =$   
330 19.0 and  $\langle ME-O \rangle_{calc} = 2.111 \text{ \AA}$ ) represents a 'mixed' species  $ME = 45\% \text{ Mg} + 38\%$   
331  $Mn^{2+} + 15\% \text{ Fe}^{3+} + 2\% \text{ Al}$ . Dashed lines mark the Mg-Mn<sup>2+</sup> and ME-M1 joins.

332

333 FIGURE 3\_  $\langle M-O \rangle$  distances calculated on the basis of the proposed cation distribution among  
334 octahedral sites plotted against the observed values. The  $\langle M1-O \rangle$  distance (1.958 Å)  
335 was used as pure  $\langle Sb^{5+}-O \rangle$ . Dashed line refers to  $y = x$  line. Data fit the following  
336 linear regression  $\langle M-O \rangle_{calc} = 1.04(5) \langle M-O \rangle_{obs} + 0.1(1)$ ,  $r^2 = 0.987$ . The  $\langle M1-O \rangle$   
337 distance (empty square) was not included in the linear model.

338

339 FIGURE 4\_ The tetrahedral  $\langle T-O \rangle$  distances plotted against the refined electron number in the  
340 T sites of filipstadite (black squares); black circles refer to data for reference bond  
341 lengths taken from literature (see Table 7) and empty triangles refer to the sum of  
342 ionic radii of four-coordinated cations and oxygen anions.

343

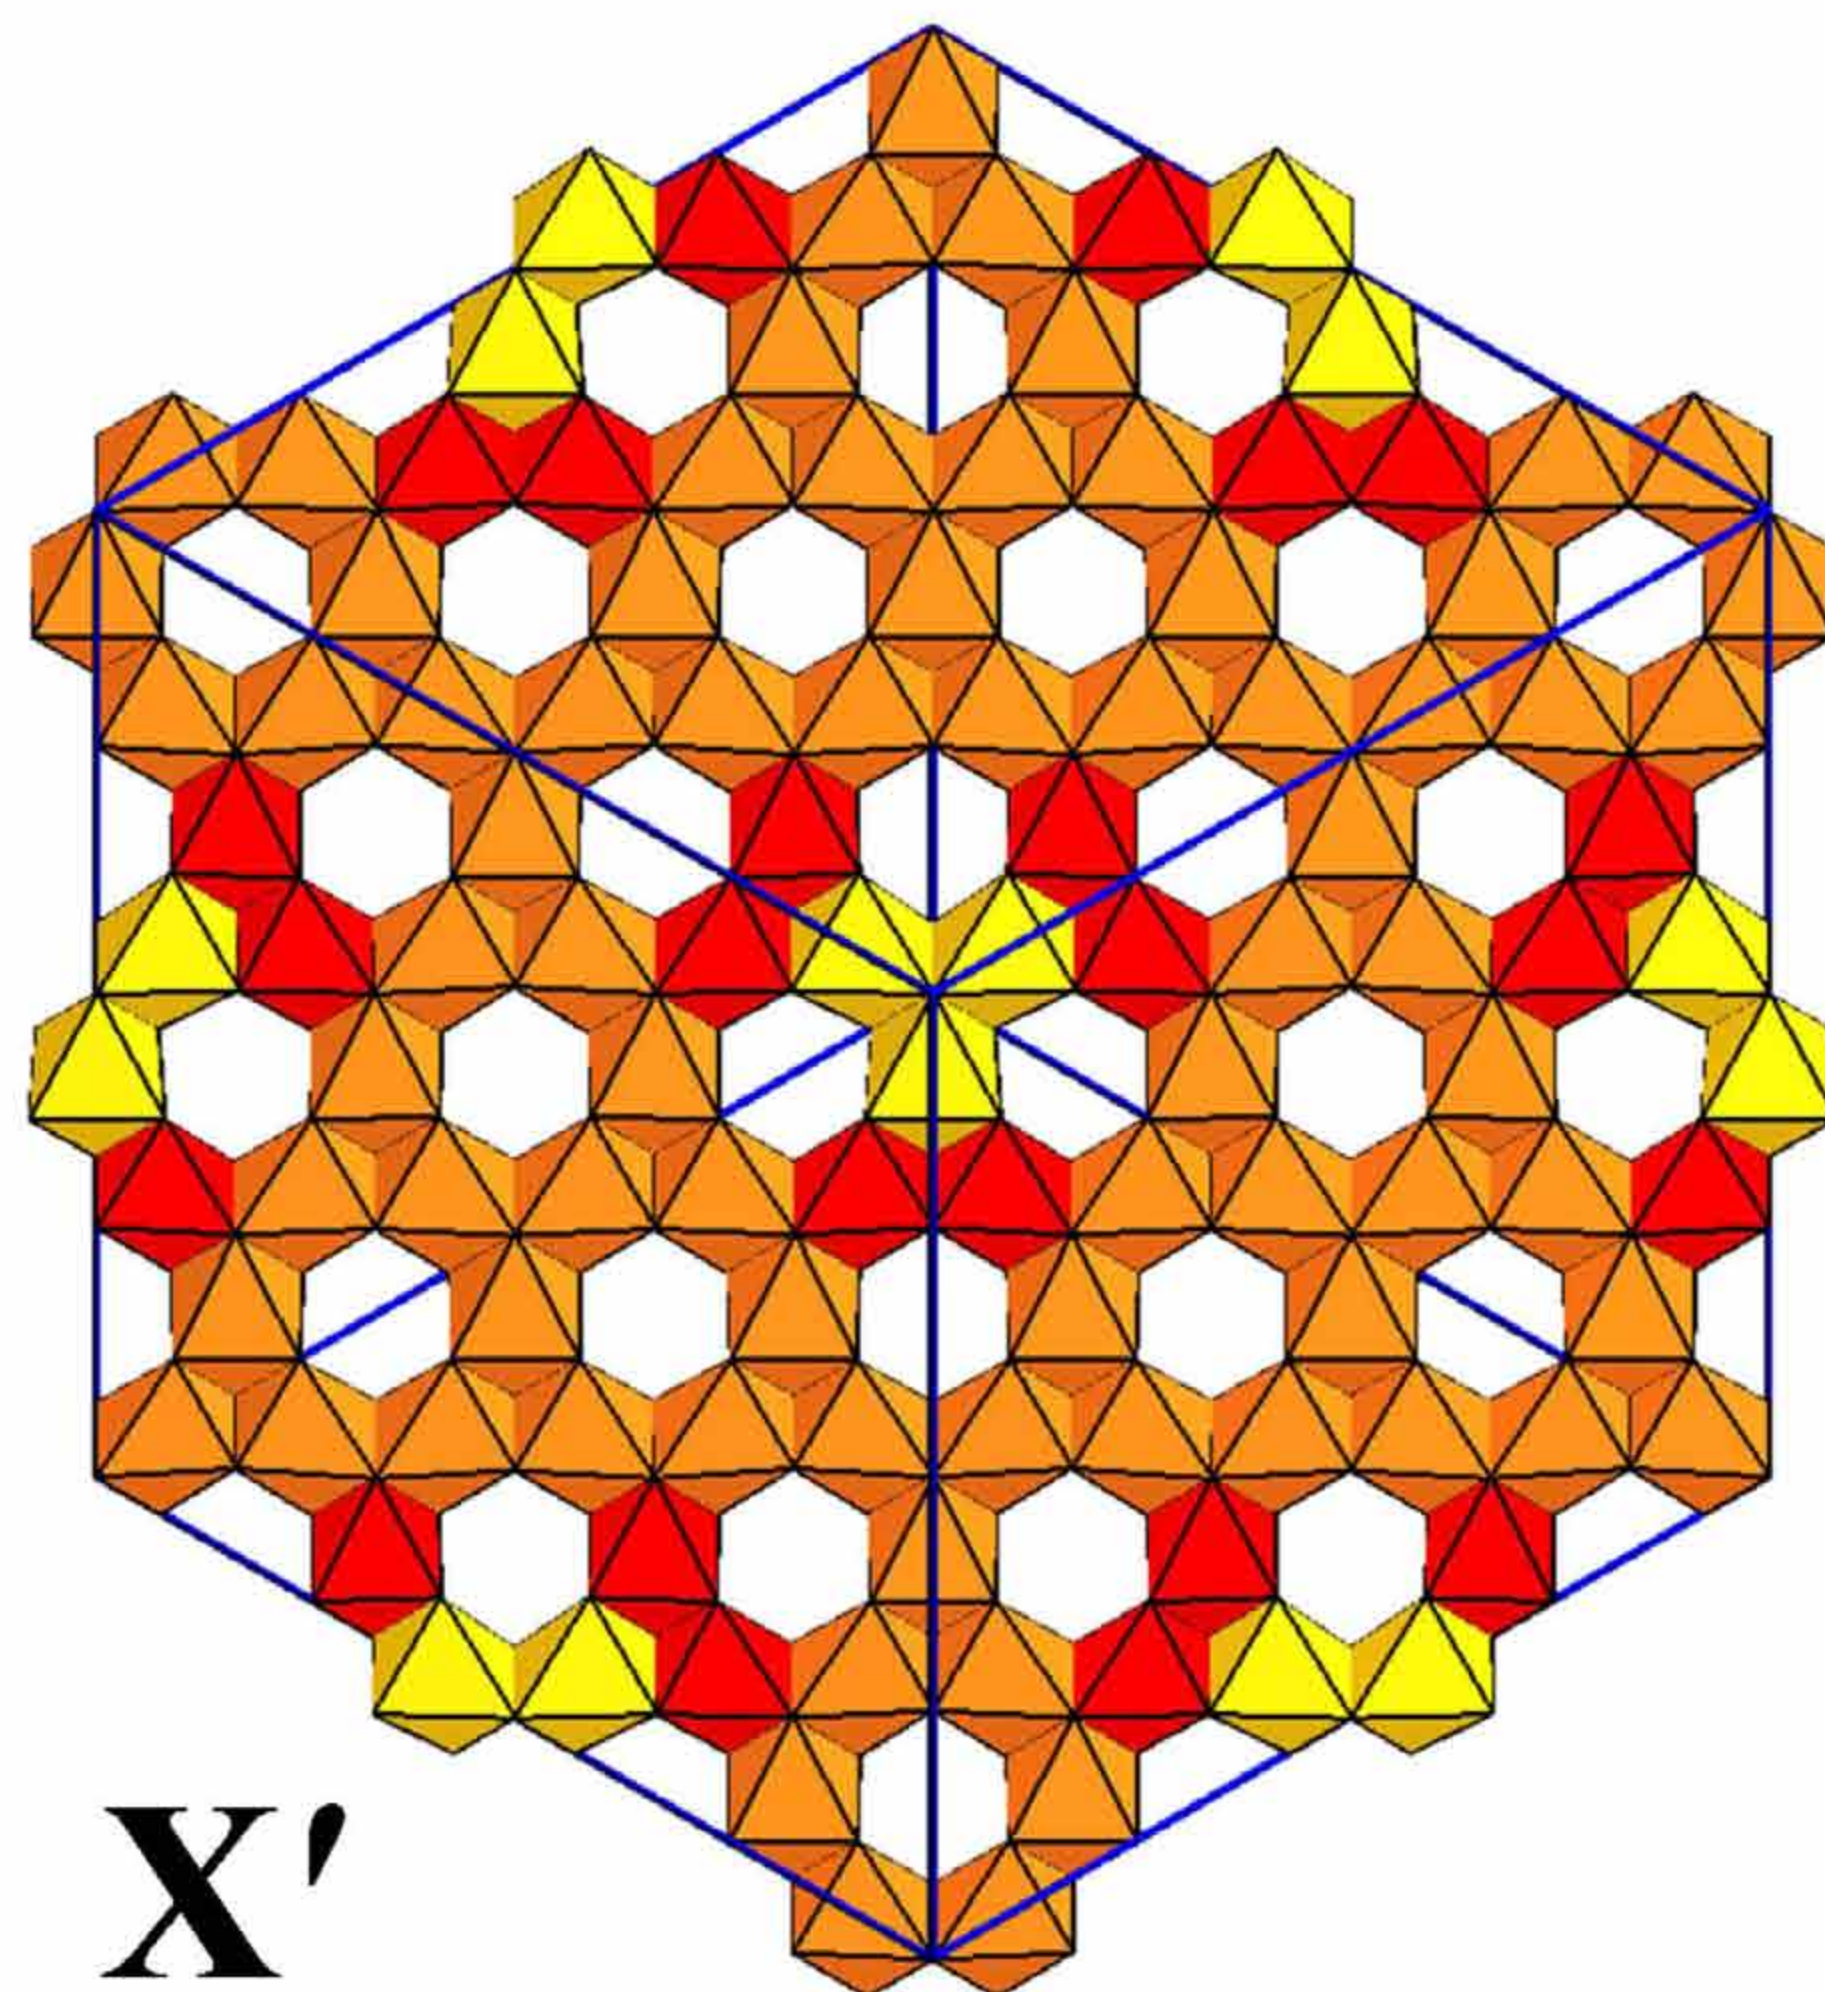

344 FIGURE 5\_ Individual T-O<sub>i</sub> distances plotted against the sum of cation charge in the three M  
345 sites bonded to each O<sub>i</sub>.

346

347 FIGURE 6\_ <T-O> distances calculated on the basis of the proposed cation distribution among  
348 tetrahedral sites plotted against the observed values. Dashed line refers to  $y = x$  line.  
349 Data fit the following linear regression  $\langle T-O \rangle_{\text{calc}} = 1.0(3)\langle T-O \rangle_{\text{obs}} - 0.0(6)$ ,  $r^2 =$   
350 0.74.

TABLE 1 – Crystallographic data and refinement parameters for filipstadite

|  |  |
|--|--|
| <b>Crystal data</b>                              |  |
| Ideal formula                                    | $(\text{Mn}^{2+}, \text{Mg})_2(\text{Sb}, \text{Fe}^{3+})\text{O}_4$ |
| Crystal system                                   | Cubic  |
| Space group                                      | $Fd\bar{3}m$ (origin #2)   |
| Unit-cell parameters $a, c$ (Å)                  | 25.9300(6)   |
| Unit-cell volume (Å <sup>3</sup> )               | 17434.4(7)   |
| $Z$  | 216  |
| Crystal size (mm)                                | 0.055×0.060×0.065  |
| <b>Data collection</b>                           |  |
| Diffractometer                                   | Oxford Diffraction Xcalibur 3  |
| Temperature (K)                                  | 298(3)   |
| Radiation, wavelength (Å)                        | $\text{MoK}\alpha$ , 0.71073   |
| $\theta_{\text{max}}$ for data collection (°)    | 32.30  |
| $h, k, l$ ranges                                 | -38 ÷ 37, -37 ÷ 20, -30 ÷ 35   |
| Detector to sample distance (cm)                 | 5  |
| Number of frames                                 | 1754   |
| Measuring time/frame (s)                         | 45   |
| Frame width (°)                                  | 0.90   |
| Total reflections collected                      | 26652  |
| Unique reflections ( $R_{\text{int}}$ )          | 1459 (4.40%)   |
| Unique reflections $F > 4\sigma(F)$              | 681  |
| Absorption correction method                     | ABSPACK (Oxford Diffraction 2006)                                    |
| <b>Structure refinement</b>                      |  |
| Refinement method                                | Full-matrix least-squares on $F^2$                                   |
| Weighting scheme                                 | $1/\sigma^2(F)$  |
| Data/restraints/parameters                       | 1459/0/110   |
| $R_1 [F > 4\sigma(F)]$                           | 4.41%  |
| $R_1$ all  | 6.42%  |
| Largest diff. peak and hole ( $e^-/\text{Å}^3$ ) | 1.17, -1.45  |

TABLE 2 – Electron microprobe analyses (wt % of oxides) and atomic ratios (on the basis of 4 oxygen atoms) for the selected filipstadite crystal.
