27   **ABSTRACT**

28

29   The effect of carbonate on the growth of barite {001} surfaces from aqueous solutions

30   supersaturated with respect to barite ($\Omega_{barite} \sim 12$) was studied by hydrothermal atomic force

31   microscopy (HAFM) and Raman spectroscopy at temperatures ranging from 25 °C to 70 °C.

32   The experiments showed that the effects of carbonate depend on the specific location of

33   growth. For mono-layers growing on pristine barite, the carbonate-additive promotes growth

34   and the spreading rate of two-dimensional islands increases with temperature. However,

35   growth is inhibited in layers growing on surfaces which grew in carbonate containing

36   solution. The threshold carbonate concentration necessary to completely inhibit growth is

37   inversely correlated with temperature. Raman spectroscopy revealed the presence of

38   carbonate within crystals which grew in carbonate containing solution. Judging by these

39   findings, incorporation of carbonate into the structure of growing barite as a thermally

40   activated process likely is a controlling factor which inhibits barite growth. Thus the study

41   shows that additives can exert opposing effects on growth not only depending on additive

42   concentration but also depending on the specific growth location. The implication of this

43   work, therefore, is that bimodal effects of additives on crystal growth occur more frequent

44   than generally recognized. The insights into the mechanisms of such bimodal effects of

45   additives can significantly contribute to the understanding and predictability of the kinetics of

46   macro-scale processes such as barite scale formation or the behavior of barium sulfate in CO_2-

47   sequestration fluids.

48

52   **INTRODUCTION**

53

54   Barite ($BaSO_4$) occurs in a wide variety of geologic environments from the early

55   Archean to the present (Hanor 2000). Due to its low solubility in water ($K_{sp} = 10^{-9.96}$ at 20 ºC,

56   Blount 1977), barite precipitation and dissolution control the geochemical distribution of

57   barium in surface waters as well as in crustal fluids. Mixing of Ba-rich hydrothermal fluids

58   with sulfate-rich meteoric or ocean fluids produces supersaturated solutions and results in a

59   rapid precipitation (Hanor 1994). Crystal growth from solution is a complex process

60   comprising of several steps from bulk diffusion to the final incorporation of the growth unit

61   (Nielsen 1984; Sunawaga 1993; Astilleros et al. 2006). Impurities in the growth medium

62   strongly influence the kinetics of growth (Sangwal 1993). Therefore, the effects of additives

63   on crystal growth kinetics have been studied extensively (Davey 1976; Davey and Mullin,

64   1974a, 1974b; Kubota and Mullin 1995; Kubota 2001; Kubota et al. 1999; Rauls et al. 2000;

65   Sangwal 1993; Sánchez-Pastor et al. 2007; Sunagawa 1987). High resolution AFM

66   investigations and numerical methods have gained insights into the molecular processes

67   leading to the observed effects (Astilleros et al. 2010; Bosbach et al. 1998; De Yoreo et al.

68   2001; Dove and Hochella 1993; Freij et al. 2004; Higgins et al. 2000; Kuwahara 2011; Pina et

69   al. 1998; Reyhani et al. 2002; Risthaus et al. 2001; Stack et al. 2012). Because carbonate is

70   one of the most important anions in meteoric waters, the effects of carbonate on the growth of

71   barite are particularly relevant. Sánchez-Pastor et al. 2006 studied the effects of carbonate at

72   room temperature and various levels of supersaturation. The study revealed that the step

73   kinematics on both {001} and {210} faces were strongly affected by the presence of

74   carbonate: While the advance of steps of the first growth layer was promoted, an increasing

75   inhibition with increasing carbonate concentration was found for the steps in the second layer.

76   Above a certain threshold concentration, step advance completely ceased i.e., a dead zone was

                                                                                                3

77   reached (c.f. Cabrera and Vermilyea 1958; Land et al. 1999; Sangwal and Owczarek 1993;

78   van Enckevort et al. 1996).

79

80   The aim of this work was to study the effects of carbonate at elevated temperatures

81   using Raman spectroscopy and hydrothermal atomic force microscopy (HAFM; c.f. Higgins

82   et al. 1998a, 1998b, 2002; Jordan and Astilleros 2006; Jordan et al. 2007; Sanchez-Pastor et

83   al. 2010) in order to obtain answers to the questions: i) How does the carbonate concentration

84   affect the growth kinetics of the first and second monolayer above room temperature? ii) Does

85   the presence of carbonate ions affect the morphology of the two dimensional islands? iii)

86   What is the temperature dependence of the threshold carbonate concentration necessary to

87   inhibit growth?

88

89   **EXPERIMENTAL PROCEDURE**

90   **HAFM experiments**

91

92   In-situ HAFM experiments were carried out on barite {001} surfaces. Optically clear

93   and colourless natural barite crystals (León, Spain) were cleaved along (001) with a razor

94   blade. Samples were mechanically mounted into the AFM fluid cell using a Ti-wire; no

95   adhesives were used. A continuous flow (> 0.2 mL/min) of solution through the fluid cell

96   (volume $\approx$ 0.5 mL) was established by a gravity feed. Temperatures ranged from 25 °C to 70

97   °C. Due to the temperature dependence of the barite solubility (Blount 1977), the

98   concentrations of Ba^{2+} and SO_4^{2-} had to be adjusted for the chosen supersaturation $\Omega_{barite} \sim 12$

99   ($\Omega_{barite} = a(Ba^{2+}) \cdot a(SO_4^{2-})/K_{sp,barite}$ where $a(Ba^{2+})$ and $a(SO_4^{2-})$ are the activities of the free ions

100   in the solution and $K_{sp,barite}$ is the barite solubility product). The according activities were

101   calculated using PHREEQC (Parkhurst and Appelo 1999). Table 1 summarises the

102   concentrations of $BaCl_2$, Na_2SO_4 and Na_2CO_3 used at 25, 40, 50, 60 and 70 °C as well as

4

103   Ω_{barite} and $\Omega_{witherite}$. All solutions were strongly undersaturated with respect to witherite. The

104   growth solutions were prepared from commercial reagent grade $BaCl_2$, Na_2SO_4 and Na_2CO_3

105   dissolved in high purity deionized water (resistivity: 18 MΩ.cm) which was equilibrated with

106   the ambient atmosphere before adding further reagents. The pH of the carbonated solutions

107   varied from 8 to 10 causing carbonate and bicarbonate to be the dominant species. Systematic

108   measurements of the step advance rates were taken on the barite surface along the [100]

109   direction of the two-dimensional islands (Fig. 1a). To ensure reproducibility, experiments

110   were repeated 2 or 3 times on different barite samples.

111

112   **Micro- Raman spectroscopy experiments**

113

114   To further characterize the influence of temperature and the possible incorporation of

115   carbonate into the structure, Raman spectroscopic analyses were performed. For this purpose,

116   natural barite crystals were cleaved along the (001) surface and placed within a batch reactor

117   (volume ~ 1000 mL). The reactor was filled with a solution supersaturated with respect to

118   barite (Ω_{barite} = 12.3, $\Omega_{witherite}$ = 0.03) and containing 0.03 mM sodium carbonate at 50 ºC

119   (carbonate speciation $a(CO_3^{2-})$ = 0.1×10^{-5} M, $a(HCO_3^-)$ = 2.8×10^{-5} M). For Raman

120   measurements, the crystals were removed from the solution after 240 hours.

121

122   Raman spectra were taken with a confocal micro-Raman spectrometer (HORIBA;

123   XploRa-Raman-System). For excitation we used the second harmonic generation (532 nm,

124   P_{max} = 15 mW) of a Nd-YAG laser, focused with a 100x long-wide-distance objective

125   (Olympus) and a beam diameter of 0.7 μm. The beam was transmitted through an optical fibre

126   to the spectrometer using a 50 μm diameter fibre core as a pinhole for the confocal setup. The

127   diffraction limited focus resulted in a lateral resolution of about 400 nm and a focal depth of

128   about 800 nm. Due to the TEM00 laser mode, the power distribution within the laser beam

5

129   profile was Gaussian. Therefore, the energy input in the central region was higher than at the

130   rim of the laser spot. A sharp edge filter removed elastically scattered photons. For the

131   measurements a 100 % filter and a 1200 T grating was used. All spectra were analyzed using

132   FITYK curve fitting and data processing software (Wojdyr 2010).

133

134   **RESULTS AND DISCUSSION**

135

136   At 25 °C, two-dimensional islands (half unit cell in height) nucleated and spread on

137   the barite (001) surface (Fig. 1a). The islands were bound by two straight edges parallel to the

138   <120> directions and one curved edge. Due to the symmetry of the barite structure, with a

139   binary screw axis perpendicular to the surface, islands on consecutive (001) layers are rotated

140   by 180° (Fig. 1b; c.f. Hartman and Strom 1989; Pina et al. 1998; Sánchez-Pastor 2006). As a

141   reference, the spreading rate of the two-dimensional islands were measured along [100] in

142   pure solutions at different temperatures (Table 1). The spreading rates increased exponentially

143   with temperature. A rate of 0.54 ± 0.01 nm/s and 4.2 ± 0.3 nm/s was measured at 25 ºC and

144   70 ºC, respectively. The increase of the velocities with temperature fits very well to an

145   Arrhenius behavior (Fig. 2) yielding an apparent activation energy E_a of 38 ± 1 kJ/mol.

146   Higgins et al. (2000) reported an effective activation energy of approx. 44 kJ/mol from

147   measured velocities of <120> bilayer steps in the temperature range of 90 to 125 °C and

148   supersaturation $1 < \Omega < 1.7$.

149

150   In carbonate containing solutions ($\Omega_{barite} \sim 12$) at 25 °C, the islands growing directly

151   on pristine barite surface showed the characteristic circular sector shape with straight edges

152   parallel to the <120> directions. Furthermore, the spreading rates of islands growing directly

153   on the pristine barite surface increased with increasing carbonate concentration and

6

154   temperature (Table 2 and Sánchez-Pastor, 2006). Above 60 ºC, the rates were so high that

155   quantitative measurements were not possible any longer.

156

157   Figure 3 shows the evolution of the barite (001) surface during the exchange of a pure

158   solution for a carbonate containing solution (total carbonate Tc = 0.06 mM) at 50 °C. Four

159   two-dimensional islands can be seen (Fig. 3a) which had been formed in the carbonate-free

160   solution. 54 minutes later (Fig. 3b), a new generation of islands was formed on the surface.

161   After the acquisition of the data shown in Figure 3b, the solution in the cell was exchanged

162   for the carbonate containing solution. Thus, the islands grew in the presence of carbonate but

163   still on pristine barite surface on which they coalesced and formed a complete monolayer

164   (Fig. 3c). The initial stage of formation of the second monolayer can be observed in Figure

165   3d. The islands of the second monolayer (marked) started to grow on those areas that had

166   been grown in the absence of carbonate (e.g. on top of the islands marked in Fig. 3b).

167   However, the shape of the new islands differs from the shape of the islands on the first

168   monolayer. In Figure 3e, the beginning of the formation of the third monolayer can be seen.

169   Steps increasingly roughened and the island morphology turned elliptical (the latter only if

170     $a(CO_3)$ >0.4x10^{-5} M and T ≥40 °C). In Figure 3f (taken 145 minutes after Fig. 3a), steady

171   state growth was established by nucleation, spreading and coalescence of islands with rough

172   elliptical steps.

173

174   In Figure 4, the spreading rates of the islands along the [100] direction within the

175   second and higher layers have been plotted versus the activity of carbonate in the solution for

176   25 °C, 40 °C, and 50 °C. Table 2 shows the according activities of the carbonate and

177   bicarbonate species. The data at 25 °C (squares) were taken from Sánchez-Pastor et al.

178   (2006). At 25 °C, the spreading rate of second layer islands was 0.54 nm/s for $a(CO_3^{2-})$

179   activities <0.7x10^{-5} M. For $a(CO_3^{2-})$ >6.6x10^{-5} M, growth of second layer islands was

7

180   completely inhibited. Islands only grew either on pristine barite or on layers previously grown

181   in the absence of carbonate. In the case of carbonated solutions at 40 °C (circles in Fig. 4), the

182   growth rate of second layer islands remained constant at ~1.3 nm/s for $a(CO_3^{2-})$ <0.1x10^{-5} M.

183   For higher activities, the rate decreased as the concentration increased. The concentration

184   required to completely inhibit growth at 40 °C was 1.4x10^{-5} M. At 50 °C, the rate in presence

185   of low carbonated solutions (triangles in Fig. 4) is approx. three times higher than at 25 °C.

186   Also at this temperature, the spreading rate decreased with increasing carbonate

187   concentration. Moreover, $a(CO_3^{2-})$ required to completely inhibit growth was 0.62x10^{-5} M.

188

189   While the spreading rate of the first layer increases with increasing carbonate

190   concentration, the findings for the second and higher layers can be summarized as follows: i)

191   at low carbonate concentrations spreading rates of two-dimensional islands increase with

192   increasing temperatures; ii) with increasing carbonate concentration spreading rates decrease;

193   iii) this decrease of rates becomes more pronounced with increasing temperature; iv) the

194   threshold carbonate concentrations to attain full inhibition decrease with increasing

195   temperature. The increasing inhibitor-effect of carbonate with increasing temperature points

196   to a thermally activated process. AFM observations revealed (Fig. 3) step roughening and

197   changes of the shape of the two-dimensional islands in carbonate containing solutions.

198   Therefore, the thermally activated inhibiting process is likely located at the surface of the

199   barite crystals. At this location CO_3^{2-} chemisorption and/or incorporation can cause the

200   observed inhibition. Chemisorption has been suggested to be the major inhibition process for

201   instance for calcite growth in the presence of Sr (Bracco et al. 2012). The effect of carbonate

202   on barite growth, however, can hardly be explained by chemisorption solely. Chemisorption

203   likely takes place on all layers to a similar extent. A uniform effect on all layers should be the

204   consequence rather than the observed layer dependent effect of carbonate.

205

8

206   Irrespective of the difference between the effects of carbonate on barite growth and Sr

207   on calcite growth, the ratio of the solution activity of the additive and the constituent ion at

208   which the spreading rate is one-half of the maximum rate can be calculated (i.e. [$a(CO_3^{2-}$

209    $)/a(SO_4^{2-})$] at $R_{max/2}$; see Bracco et al. 2012). However, the temperature dependent CO_3^{2-}/SO_4^{2-}

210   -data obtained here allow further evaluation by plotting the logarithm of the CO_3^{2-}/SO_4^{2-}-

211   ratios at half spreading rate vs. reciprocal absolute temperature (Fig. 5). The plot shows a

212   linear relationship. Following the reasoning of Bracco et al. (2006), a free energy of carbonate

213   incorporation of $\Delta G = -40\pm3$ kJ/mol can be derived from the slope of the linear relation. The

214   similarity of this value and the apparent activation energy for step advancement (see above)

215   supports the assumption of competitive incorporation of carbonate and sulfate.

216

217   In order to clarify whether the growing barite crystal incorporates significant amounts

218   of carbonate, micro-Raman spectroscopic analyses were performed on pristine barite crystals

219   and on samples which grew in carbonate containing solutions at 50 ºC. The data are listed in

220   Table 3. The Raman spectra of the barite samples were dominated by an intense ν_1 band

221   (symmetric stretching) of SO_4 tetrahedra at 989 cm^{-1} (Fig. 6). The other characteristic bands,

222   ν_2, ν_3 and ν_4 reported in literature (Dimova et al. 2006; Chen et al. 2009; Sánchez-Pastor et al.

223   2011) were also present (Fig. 6; Table 3). The ν_2 vibration (in-plane bending) generated bands

224   in the 400–500 cm^{-1} region, the ν_4 vibration (out-of-plane bending) generated bands in the

225   600–700 cm^{-1} region, and the ν_3 vibration (asymmetric stretching) generated bands in the

226   1080–1200 cm^{-1} region. Figure 6 shows these regions for a pristine barite (barite_pure, grey

227   data) and a crystal that was treated with the growth solution at 50 ºC (barite_c, black data). In

228   both cases, the Raman bands are approximately in the same positions. However, it should be

229   noted that the Raman spectra of crystals are anisotropic. That is, the band positions and

230   relative band intensities may vary slightly depending on the crystal lattice orientation. Figure

231   7 shows a section of the Raman spectra with the ν_3 band decomposition for the pristine barite

9

232   (barite_pure, grey data) and the treated barite (barite_c, black data). Moreover, the Raman

233   spectrum of a natural witherite aggregate has been superimposed. The bands at 1084 cm^{-1},

234   1106 cm^{-1}, 1140 cm^{-1} and 1168 cm^{-1} are characteristic of Raman spectra of pure barite and are

235   present in both barite spectra. However, the Raman spectrum of the treated barite shows an

236   additional band at 1059 cm^{-1}. This band was exclusively observed at barite samples which

237   grew in carbonate containing solution and corresponds to the ν_1 internal mode (symmetric

238   stretching) of witherite. Therefore, the band is conclusive for the presence of carbonate groups

239   incorporated within the barite lattice.

240

241   On the basis of this finding we speculate that the different effects of carbonate are not

242   only caused by (temporarily) chemisorbed complexes but also by incorporation of carbonate

243   into the barite structure. This two-fold mechanism gives rise to the different growth behavior

244   of islands growing on the pristine barite surface on the one hand and on a barite surface with

245   incorporated carbonate on the other hand. Whereas growth promotion of layers on pristine

246   barite reflects the effects of chemisorption and incorporation, the growth inhibition of

247   subsequent layers is additionally affected by substrate alteration. This alteration is a

248   consequence of carbonate incorporation during growth of the substrate and is the major cause

249   for the observed growth inhibition. Because spreading rates on pristine barite in the presence

250   of carbonate are directly correlated with temperature, we speculate that substrate alteration is

251   a thermally activated process and controls the inverse correlation of temperature and dead

252   zone threshold concentration.

253

254   The study is a further example revealing that a single additive can exert opposing

255   effects on crystal growth. Whereas, for example, silicic acids (Pina et al. 2009) or

256   polyaspartate (Elhadj et al. 2006) show an opposing effect on calcite growth depending on

257   additive concentration, the opposing effect of carbonate on barite growth depends on the

10

258   specific location of the growth layer. The so called "template effect" (e.g., Astilleros et al.

259   2010) similarly denotes a location-dependent effect of an additive but does not necessarily

260   imply opposing promotion and inhibition.

17

438   **List of Figure Captions**

439

440   **Figure 1.** AFM images of two-dimensional islands growing on a barite (001) surface at Ω_{barite}

441   = 12, and T = 25°C. (a) Spreading rates of the islands were measured along the [100]

442   directions. (b) Height image showing islands rotated by 180° which were nucleating in the

443   next adjacent monolayer.

444

445   **Figure 2.** Plot of the spreading rates of two-dimensional islands along the [100] direction in

446   pure solutions against 1/T. The linear fit yields an apparent activation energy *Ea* of 38 ± 1

447   kJ/mol. (R^2 = 0.9979).

448

449   **Figure 3.** Growth sequence of the barite (001) surface (T = 50°C) in the absence and in the

450   presence of carbonate (*Tc* = 0.06 mM). (a) In the absence of carbonate. (b) The surface is in

451   contact with the carbonate containing solution. (c) The islands on the pristine barite substrate

452   coalesce and complete a monolayer. (d) On the areas that were previously grown in the

453   absence of carbonate, the formation of a new generation of irregular-shape islands can be

454   observed (islands indicated with arrows). (e) When the islands corresponding to the second

455   layer reached a substrate area which grew from a carbonate containing solution, their

456   spreading rate decreased and the shape of the islands changes to elliptical. (f) Carbonate

457   increased the stability of the steps parallel to the [110] direction.

458

459   **Figure 4.** Spreading rates along [100] of two-dimensional islands growing on areas

460   previously grown in the presence of carbonate versus the total carbonate concentration in the

461   aqueous solution. Squares, circles and triangles correspond to 25 °C, 40 °C and 50 °C,

462   respectively.

463

18

464   **Figure 5.** Plot of the logarithm of the CO_3^{2-}/SO_4^{2-}-ratios at half spreading rate against the

465   reciprocal absolute temperature. The linear fit yields a free energy of carbonate incorporation

466   of $\Delta G = -40 \pm 3$ kJ/mol.

467

468   **Figure 6.** Raman spectra of pristine barite (barite_pure) and barite crystals which grew in

469   carbonate containing solutions (barite_c) showing the dominant Raman band due to the

470   symmetric stretching (ν_1 vibration) of SO_4 located at $\sim$989 cm^{-1}. The ν_2 vibration (in-plane

471   bending) generates bands in the $400 - 500$ cm^{-1} region, the ν_4 vibration (out-of-plane

472   bending) generates bands in the $600 - 700$ cm^{-1} region, and the ν_3 vibration (asymmetric

473   stretching) generates bands in the $1100 - 1200$ cm^{-1} region. Moreover, the characteristic

474   Raman bands due to the external vibration modes are located in the $50 - 250$ cm^{-1} region.

475

476   **Figure 7.** Raman spectra of the ν_3 vibration region of the S-O showing the characteristic

477   bands. In the spectrum of barite crystals which grew in carbonate containing solutions

478   (barite_c), an additional band at $\sim$1059 cm^{-1} can be observed. This band corresponds to the

479   symmetric stretching (ν_1 vibration) of CO_3.

480

19

481   **Tables**

482

483   **Table 1.** Experimental parameters and spreading rates R of two-dimensional islands in pure

484   solutions and in solutions containing the minimum amount of carbonate resulting in complete

485   growth inhibition (marked with an asterisk).
