25

26 **Abstract**

27 Single-crystal diffraction of jarosite, $KFe^{3+}_3(SO_4)_2(OH)_6$, has been undertaken at low

28 temperatures that proxy for Martian surface conditions. Room temperature data is consistent

29 with literature data ($a = 7.2913(5)$, $c = 17.1744(17)$ and $V = 790.72(11)$ in R-$3m$), while the

30 first low temperature data for the mineral is presented (at 253, 213, 173 and 133K). Data

31 collections between 297 and 133 K show strongly anisotropic thermal expansion, with the **c**

32 axis much more expandable than the **a** axis. Much of the anisotropy is due to strong distortion

33 of the KO_{12} polyhedron, which increases by 8 % between 297 and 133 K. The datasets can

34 aid in the identification of jarosite by X-ray diffraction of Martian soils using the Curiosity

35 Rover's CheMin instrument.

36

37 Keywords: crystal structure, low temperature, jarosite, Mars, anisotropy, alunite supergroup.

38

39 **Introduction**

40 Jarosite, $KFe^{3+}_3(SO_4)_2(OH)_6$ (Mills et al. 2009a; Bayliss et al. 2010), has always been a

41 mineral of great interest to mineral scientists, because of its relevance to many areas such as

42 acid mine drainage (e.g., Nordstrom et al. 2000; Welch et al. 2007, 2008, 2009), the mobility

43 of toxic elements (e.g., Kolitsch & Pring 2001) and metallurgical processing (e.g., Dutrizac &

44 Jambor 2000). But it is its discovery on Mars (Klingelhöfer et al. 2004; Farrand et al. 2009)

45 in particular, which has caused a renaissance in research about the formation and stability of

46 the mineral (e.g., Navrotsky et al. 2005; Papike et al. 2006; Golden et al. 2008) and its

47 structural analogues (e.g., Grey et al. 2008, 2009, 2011, 2013; Mills et al. 2010; Scarlett et al.

48 2010, 2013). Despite this, very few single crystal refinements of jarosite have been made, and

49 none at low temperature. The lack of low-temperature data for jarosite is important, in this

50 case, because the CheMin (Chemistry & Mineralogy X-Ray Diffraction) instrument on the

51   Curiosity Rover is designed to identify minerals by X-ray diffraction and chemical analysis

52   (Grotzinger et al. 2012), and the surface temperature on Mars is low enough to cause

53   significant change in cell parameters from room-temperature values, or even to drive

54   minerals through phase transitions. The global mean surface temperature is ~202 K (Haberle

55   2013), while local temperatures may lie within the range of at least 143–273 K (Herri &

56   Chassefière 2012). We note that the wide range of low temperatures on Mars may also have

57   significant effects on other measurements (e.g. spectroscopic) used for detection and

58   identification of minerals such as jarosite.

59

60   Jarosite is a member of the large alunite supergroup of minerals (Mills et al. 2009a; Bayliss et

61   al. 2010), and participates in a wide range of solid solutions where the K^+ may be replaced by

62   other species such as Na^+ or H_3O^+, Fe^{3+} by Al^{3+}, and S^{6+} by P^{5+} or As^{5+}. Furthermore,

63   members of the supergroup may deviate from the ideal $AB_3(TO_4)_2X_6$ stoichiometry. There

64   may be vacancies on the large interlayer A sites (as in plumbojarosite,

65    $(Pb_{0.5}\square_{0.5})Fe_3(SO_4)_2(OH)_6$ — Szymański, 1985; Mills et al. 2009b), interstitial small cations

66   (kolitschite, $PbZn_{0.5}Fe_3(AsO_4)_2(OH)_6$ — Mills et al. 2008; Grey et al. 2008) or, in material

67   synthesised at low temperatures, vacancies on the octahedral B sites (Scarlett et al. 2010;

68   Grey et al. 2011). In the latter two cases, ordering of the defects reduces the symmetry from

69   rhombohedral to C-centred monoclinic. The unit cell parameters vary significantly with all of

70   these substitutions, although the a-axis is more sensitive to the content of the B site and the c-

71   axis to the content of the interlayer A site (cf. Drouet et al. 2004).

72

73   It is likely that some "jarosite" minerals present on Mars depart considerably from the end-

74   member jarosite studied here. Morris et al. (2006) indicate that for samples examined at

75   Meridiani Planum, at least, $Na^+ > K^+ > H_3O^+$ with possible Al^{3+} substitution for Fe^{3+}. This

76   implies that mineral is not jarosite *sensu stricto* but natrojarosite, with solid solution towards

77   jarosite, hydroniumjarosite and natroalunite. Milliken et al. (2013) report infrared spectra

78   from the region of Ius and Melas Chasmata that they interpret as from H_3O-bearing, Fe-

79   deficient jarosite. The simulated Martian acid-sulfate alteration experiments of McCollom *et*

80   *al*. (2013a,b) suggest that the alunite-supergroup phase formed by alteration of mafic

81   pyroclastics should be Fe-rich natroalunite, rather than jarosite. Hence, a range of alunite-

82   supergroup solid solutions may be present on Mars. Physical properties, including

83   temperature-dependent diffraction behaviour, can most easily be estimated for such

84   compositionally intermediate phases by interpolation from good-quality data for the end-

85   members. This paper constitutes a first step in the assembly of a dataset suitable for such

86   interpolation, where we have investigated the single crystal structure of a sample of natural

87   jarosite between 297 and 133 K, covering the range of surface temperatures experienced by

88   Mars.

89

90   **Experimental**

91   *Sample*

92   Although an analysis corresponding to jarosite was first reported from lignite seams at

93   Kolosuruk (Korozluky, Czech Republic) by Rammelsberg (1838), he referred to the mineral

94   only as "gelbeisenerz" (yellow iron ore). The first use of the name 'Jarosit' for the mineral

95   was by Breithaupt (1852) for material from the Jaroso Ravine, Sierra Almagrera, Andalusia,

96   Almeria, Spain, which is therefore regarded as the type locality. The sample of endmember

97   $KFe^{3+}_3(SO_4)_2(OH)_6$ jarosite used in the study (M20912) was from the type locality and was

98   obtained by Museum Victoria from Dr August Krantz in the 1850s. Thus, this specimen

99   would have not been collected long after the type description was published. The specimen

100 consists of clusters of honey-brown crystals up to about 1 mm across, coating cavities in

101 massive hematite rock. Several crystals were selected then used for the single crystal study.

102 The jarosite hematite association is prevalent on Mars, the most notable example being that

103 at Meridiani Planum (Klingelhöfer et al. 2004; Golden et al. 2008).

104

105 *X-ray diffraction*

106 A prismatic brownish-transparent single-crystal (dimensions: 0.04 x 0.05 x 0.09 mm) of good

107 optical quality when observed under a petrographic microscope was selected for the X-

108 diffraction experiments and mounted on the tip of a glass fibre using nail polish. X-ray

109 diffraction data were acquired at five temperatures (297, 253, 213, 173 and 133 K) with an

110 Oxford Diffraction Gemini-R Ultra diffractometer equipped with a Ruby CCD detector and

111 graphite-monochromated MoK_α radiation. For the low-temperature studies, the crystal was

112 cooled using an Oxford Cryosystems 700 Plus open-flow nitrogen gas device. The absolute

113 temperature uncertainty of this device, determined from a series of calibration experiments, is

114 about 1.5 K. Temperature stability during the data collection was ± 0.2 K. Integration and

115 data reduction, including Lorentz-polarization as well as a semi-empirical absorption

116 correction, were performed with the CrysAlis software package. Over the whole temperature

117 range, the crystal diffraction spots could be indexed on the *R*-centred trigonal unit cell typical

118 for jarosite. No indications of a structural phase transformation were observed. A detailed

119 summary of the data collection strategy can be found in **Table 1**. Fractional coordinates and

120 atom displacement parameters are provided in **Table 2**, and selected interatomic distances in

121 **Table 3**.

122

123 **Results**

124 Jarosite has a rhombohedral alunite-type structure (e.g. Blount, 1974), consisting of layers

125 parallel to (0001) of corner-sharing $FeO_2(OH)_4$ octahedra and SO_4 tetrahedra, stacked along

126   **c**. K atoms at the origin of the cell are in 12-fold coordination. The $Fe(O,OH)_6$ octahedra each

127   share corners with four neighbours via the OH^- anions to form a planar kagomé network with

128   3- and 6-fold rings, which can also be described as hexagonal tungsten bronze (HTB)-type

129   layers (**Fig. 1**). The O^{2-} anions of the $Fe(O,OH)_6$ octahedra in each 3-ring link to a sulfur

130   either above or below the plane of the Fe layer. Successive layers are interconnected via

131   hydrogen bonds from H to sulfate O1 of an adjacent layer, as well as through weak K   O

132   bonds. The room temperature dataset (297 K) is consistent with those reported for

133   refinements of jarosite with a similar composition: <K   O> is 2.896, <Fe   O> is 2.006 and

134   <S   O> is 1.477 Å, compared to 2.876, 2.004 and 1.498 Å, respectively for

135    $K_{0.953}H_3O_{0.047}Fe^{3+}_3(SO_4)_2(OH)_6$ (Basciano & Peterson 2007). Note that the long S   O bond

136   length in $K_{0.953}H_3O_{0.047}Fe^{3+}_3(SO_4)_2(OH)_6$ may be an artefact due to refining powder data

137   using the Rietveld method.

138

139   The low-temperature investigation performed in this study reveals a very strong anisotropy in

140   the thermal expansion of jarosite, with the *c*-axis being much more expandable than the *a*-

141   axis. **Table 4** shows the variation of the two cell parameters as a function of temperature. The

142   *a*-axis length remains practically unchanged over the temperature range investigated (0.0024

143   Å = 0.03% relative variation between maximum and minimum values), although what

144   variation there is appears to be non-montonic, with positive expansivity at low temperature

145   up to a maximum *a* parameter near 253 K, and then negative expansivity to 297 K (**Table 4**).

146   The changes are small, but the possible change in sign of expansivity merits further study.

147   The *c*-axis however, decreases in length with decreasing temperature by about 0.072 Å,

148   monotonically but with distinct curvature. **Figure 2a** shows the evolution with temperature of

149   the two axes. The *y* scale is the same for the two axes, in order to emphasise the difference in

150   absolute expansivity along the two axes. In **Figure 2b,** the unit cell volume is plotted against

151 temperature, showing a decrease by about 4.0 $Å^3$ (~0.5 %) from 297 to 133 K that is almost

152 linear with temperature, due to the curvatures of a-T and c-T trends compensating for each

153 other.

154

155 A linear approximation to the volume thermal expansion can be calculated as $\alpha_V = [(V - V_0) /$

156 $V_0]/\Delta T$ (e.g. Cameron et al. 1973). For our sample and a ΔT calculated between 297 and 133

157 K we obtain $\alpha_V = 3.10(5) \times 10^{-5} K^{-1}$.

158

159 The cell parameters of this study extrapolate to significantly smaller values at very low

160 temperatures than those obtained by Inami et al. (2000) using powder neutron diffraction at

161 10 K (a = 7.2999(3) Å and c = 7.3013(8) Å) and on deuterated material at 7 K (a = 7.3013(8)

162 Å and c = 17.097(1) Å). However, they note that there is a transition into a long-range

163 ordered antiferromagnetic state at 65 K, and associated structural relaxation may account for

164 the discrepancy. Conversely, our 297 K data are in good agreement with the 298 K data from

165 the powder neutron diffraction study of Xu et al. (2010), and our plots of **c** and V against

166 temperature (Figure 2a,b) extrapolate into theirs for the range T = 298–575 K with only slight

167 breaks in slope. Our a-axis at 297 K is also close to that of Xu et al. (2010), however, our

168 data do not lie on their trend for $T \geq 350$ K of **a** increasing nonlinearly with T. The a-axis of

169 Xu et al. (2010) increases by only 0.09 % over 350–575 K, while **c** increases an order of

170 magnitude more (0.91 %), so the extreme anisotropy in expansion is maintained to high

171 temperatures. In combination, the datasets of Inami et al. (2000), Xu et al. (2010) and this

172 study, suggest that the jarosite a-axis reaches a minimum value near 300 K, varies by only a

173 small amount, but possibly in a complex fashion, over the temperature range of our study,

174 and increases again below the magnetic transition at 65 K.

175

176   In order to explain the strong axial anisotropy, and, generally, the behaviour as a function of

177   temperature, a careful analysis of the evolution of the jarosite crystal structure is necessary.

178   Examination of the bond lengths indicates that <K O> shows the largest variation (a

179   decrease by about 0.4%, **Table 3**), while <Fe O> remains practically constant and <S O>

180   shows an increase with decreasing T (by about 0.3 %). The analysis of the site polyhedron

181   volumes (calculated using the software IVTON by Balić-Žunić and Vickovic 1996) confirm

182   the trends shown by the bond lengths. Over the range 297 133 K, the KO_{12} polyhedron

183   decreases in volume by about 1 %, the FeO_6 polyhedron does not show significant variation,

184   and the SO_4 tetrahedron increases its volume by about 0.8 %. **Figure 3** shows the evolution

185   of KO_{12}, FeO_6 and SO_4 volumes with T.

186

187   We also consider the temperature evolution of distortion for these polyhedra. The volume

188   distortion parameter used here quantifies the volume deficit of the polyhedron as compared to

189   an ideal equivalent. First, a sphere of best fit is found for the real polyhedron and the ratio of

190   sphere volume to polyhedron volume V_s/V_r calculated (Balić-Žunić and Makovicky 1996;

191   Balić-Žunić 2007). Ideal polyhedra are chosen for reference, which in this case are the

192   regular tetrahedron, regular octahedron and regular cuboctahedron for S, Fe and K

193   respectively. The volume ratios V_s/V_i are calculated for these shapes inscribed in a sphere,

194   and the distortion $\upsilon = 1 − (V_s/V_i)/(V_s/V_r)$ (Makovicky and Balić-Žunić 1998; Nestola et al.

195   2008). The advantage of this parameter is that it measures only distortions due to the

196   arrangement of atoms forming the vertices of the polyhedron alone, and decouples these from

197   distortion due to the relative position of the central atom and surrounding atoms. As a result,

198   the volume distortion can even be calculated for structural voids when necessary.

199

200   An analysis of the polyhedron volume of the KO_{12} polyhedron shows that it is extremely

201   distorted (distortion at 297 K = 0.0168, **Table 3**) and that its distortion decreases with

202   decreasing the temperature by about 8 % (**Figure 4a**). The distortion of the KO_{12} polyhedron

203   is strongly related to the polyhedron volume behaviour (**Figure 4b**). Plotting the KO_{12}

204   volume against the *c*-axis (the most compressible one) shows a strong relation (**Figure 4c**)

205   and that the contraction along the *c*-axis is governed not only by the volume decrease of the

206   KO_{12} polyhedron but also by its volume distortion.

207

208   The FeO_6 octahedron is much more regular than KO_{12}, distortion of the FeO_6 being an order

209   of magnitude lower: 0.0014 at 297 K (**Table 3**). More importantly, it does not show any

210   variation over the temperature range investigated (**Table 3**). The SO_4 tetrahedron shows

211   negligible volume distortion at all temperatures.

212

213   **Implications**

214

215   Given the significant change in the jarosite unit cell over the temperature range of this study,

216   this dataset can aid in the identification of the mineral via X-ray diffraction of Martian soils

217   using the Curiosity Rover's CheMin instrument. It is important to note, however, that

218   extensive solid solutions occur between members of the alunite supergroup, so further studies

219   on natrojarosite, natroalunite, alunite and hydroniumjarosite at low temperature will be

220   required to generate a broad crystallographic dataset which will cover the range of

221   compositions likely to be present, and to allow correct mineral assignment of Martian

222   "jarosites". Furthermore, elemental analysis will be desirable to confirm such identifications,

223   and spectroscopic methods are required to identify the H_3O^+ ion, which readily substitutes for

224   K^+.

Figure Captions

Figure 1. (a) Structural layer of jarosite viewed down **c** axis, showing $FeO_2(OH)_4$ octahedra corner-linked to form kagomé net, and triangles of octahedra linked to SO_4 tetrahedra above or below the plane of the layer. Hydrogen atoms indicated by small spheres; outlines of unit cells are dashed. (b) Unit cell of jarosite viewed approximately down [110], showing portions of three layers of the type shown in (a). SO_4 tetrahedra point up into the hexagonal holes in the layer above, or down into the hexagonal holes of the layer below. O-H vectors are directed at apical sulfate oxygens of adjacent layers. Large spheres are 12-coordinated interlayer K^+ ions.

Figure 2. (a) Temperature evolution of *a* and *c* parameters of jarosite. Estimated errors are smaller than symbols used. (b) Variation of unit cell volume with temperature for jarosite.

Figure 3. Variation with temperature of (a) KO_{12} polyhedral volume, (b) FeO_6 polyhedral volume, (c) SO_4 polyhedral volume.

Figure 4. (a) Variation of KO_{12} polyhedral distortion parameter with temperature. (b) Linear correlation between KO_{12} polyhedral volume and distortion parameter. (c) Linear correlation between KO_{12} polyhedral volume and unit cell *c* parameter.

426 Table 1: Data collection and structure refinement details for jarosite.
