**ABSTRACT**

Two samples from the enigmatic Ni-oxide body of Bon Accord (Barberton greenstone belt, South Africa) have been investigated with the hydroseparation technique in order to obtain heavy mineral concentrates. The concentrates contain abundant Pt, Pd and gold minerals never reported before from the Bon Accord Ni-oxide body. The grains occur as: i) minute inclusions (<3 micrometers) in trevorite (ideally  $\text{NiFe}^{3+}\text{O}_4$ ) and ii) larger (5–70 micrometers) free aggregates liberated from the host phase. The first group comprises a number of PGM compounds of Pd-Sb, Pd-Sb-As, Pd-Cu-Sb, Pt-Sb, Pt-As-S, Ru-As-S, Ru-S, along with free grains of Ni-Fe-As. The second consists of sperrylite ( $\text{PtAs}_2$ ), members of the sobolevskite-kotulskite series, and electrum. These results are in good agreement with previous analyses of PGE-Au in bulk rock. Paragenetic relationships indicate that the PGM and electrum are of secondary origin, probably generated during low-temperature metamorphism of the Ni-rich mineralization. They have a terrestrial origin and are related with a low-sulfidation regime that usually accompanies

32 hydrothermally driven serpentinization of mafic-ultramafic bodies. The ligands in the newly  
33 formed PGM (As, Sb, Bi, Te, O) probably proceed from the same source of the hydrothermal  
34 solutions. In this model, the metals Ni-PGE-Au were original components of the primary mineral  
35 assemblage of the Bon Accord precursor, whereas As, Sb, Bi, Te, O might have been contributed  
36 by the metasomatizing fluids, during near-surface evolution of the ore body. The data on the  
37 high-grade heavy mineral concentrates, obtained by hydroseparation, have provided new  
38 knowledge about the mineral department of Pd, Pt and Au.

44

## INTRODUCTION

45 Platinum-group minerals (PGM) are the carriers of the platinum-group elements (PGE):  
46 osmium (Os), iridium (Ir), ruthenium (Ru), rhodium (Rh), platinum (Pt) and palladium (Pd).  
47 These elements, with a concentration of about  $10^{-6}$  to  $10^{-10}\%$  in the Earth's crust, are numbered  
48 among the ultra-trace elements. They occur naturally as alloys, native elements or in  
49 combination with other elements, mainly S, As, Te, Bi, Sb, Hg, Se, Sn (see Cabri 2002) and  
50 more rarely with O (Cabri et al. 1981; Garuti et al. 1997; Garuti and Zaccarini, 1997; Jedwab and  
51 Cassedanne 1998; McDonald et al. 1999; Uysal et al. 2009). PGM are rare, representing less than  
52 3% of the minerals approved by the Commission on New Minerals and Mineral Names of the  
53 International Mineralogical Association (IMA). According to Daltry and Wilson (1997), only 96  
54 phases containing the PGE as major components were approved before 1997. These authors also  
55 listed more than 500 different chemical compositions of PGE-bearing phases that, very likely,  
56 correspond to new mineral species. However, since 1997, only 28 new PGM have been approved  
57 (Barkov et al. 2002a;b; Cabri 2002; Stanley et al. 2002; Paar et al. 2004; 2005; Rudashevsky et  
58 al. 2004; Cabri et al. 2005b; McDonald et al. 2005; 2010; Botelho et al. 2006; Kojonen et al.  
59 2007; Mochalov et al. 2007; Yu et al. 2009; Vymazalova et al. 2009; 2012a;b). The failure in the  
60 identification of PGM is due mainly to their mode of occurrence as minute inclusions (usually  
61 less than 100 micrometers in size) which are randomly distributed in their host rocks, thus  
62 severely limiting conventional crystallographic characterization by X-ray spectrometry, as

63 discussed below.

64 Traditionally the PGM are located on polished section by reflected light or electron  
65 microscope and investigated *in situ*. Usually, the identification of the mineral species cannot be  
66 done on a simple determination of the optical properties owing to the small size of grains, and is  
67 dependent on the use of electron microprobe analysis. Furthermore, although the *in situ* study  
68 provides useful information on paragenetical relationships of the PGM, it commonly does not  
69 allow a complete picture of their abundance and distribution throughout their host rock. Polished  
70 sections represent only a small portion of the host rocks, and it is known that two-dimensional  
71 counting of three-dimensionally distributed grains in solids may produce statistically deficient  
72 results (Oberthür et al. 2008; Cabri 2012; Shi et al. 2013). This is particularly critical when the  
73 subsidiary phases are unevenly dispersed and occupy extremely small volumes within the host,  
74 and for this reason they can be easily missed in any particular section. To remedy these  
75 problems, an innovative hydroseparation technique able to extract the PGM from their matrix,  
76 and concentrate them, has been recently applied successfully to a number of natural occurrences  
77 (Rudashevsky et al. 2002; 2004; Cabri et al. 2005a,b; Grammatikopoulos et al. 2007; Kapsiotis  
78 et al. 2009; Zaccarini et al. 2009; McDonald et al. 2010).

79 This paper reports on the discovery of a complex PGM and gold assemblage, obtained by  
80 application of the hydroseparation technique to a suite of samples from the enigmatic Bon  
81 Accord Ni-oxide body (Mpumalanga Province, South Africa). Internal texture and composition  
82 of encountered minerals have been documented through detailed study by field emission electron  
83 microscopy (FE-SEM) and electron microprobe analyses.

84

85

86

#### PREVIOUS STUDIES ON BON ACCORD

87 The Bon Accord Ni-oxide body was discovered in the 1920s, in the northwestern sector  
88 of the Archaean Barberton greenstone belt. It attracted attention because of its unusually high  
89 (>35% whole rock) NiO values (Trevor 1920; Walker 1923; Partridge 1944), and the entire mass  
90 was removed for processing, leaving a hole approximately 6 m<sup>3</sup> in size (De Waal 1978). After  
91 the disappointing discovery that the material was too refractory to smelt, the ore was discarded as  
92 waste about 3 km from the original outcrop location. Unfortunately, none of the material was left  
93 *in situ*.

94 The origin of the Bon Accord Ni-oxide body has been debated for three decades. De  
95 Waal (1978) interpreted it as an oxidized remnant of an Archaean iron meteorite, while Tredoux  
96 et al. (1989) proposed that it is a strongly altered deep mantle fragment within the mantle section  
97 of the Archaean Jamestown ophiolite described by de Wit et al. (1987): Mineral chemical  
98 similarities between chromite grains in the Bon Accord Ni-rich mineralization and those in the  
99 surrounding ultramafite, which they interpreted as being suggestive of a cogenetic history,  
100 prompted Tredoux et al. (1989) to reject the meteorite hypothesis of De Waal (1978). The  
101 terrestrial nature of the Bon Accord Ni-oxide body was supported recently by Cr isotopic data  
102 (Tredoux et al. 2013), but proof of a deep mantle origin remains elusive.

103 Besides the high concentrations of Ni, the Bon Accord Ni-oxide body is also enriched in  
104 PGE and contains appreciable amount of Au (Tredoux et al. 1989) (Table 1). However, to date  
105 only three grains of ruthenium, less than two micrometers in size (Fig. 1), have been discovered  
106 in the Bon Accord Ni-oxide body using traditional petrographic methodology (Tredoux et al.  
107 2014, submitted). The data presented in this paper demonstrate that the PGM assemblage is  
108 much more complex than previously supposed, and that the PGM are accompanied by significant  
109 amount of gold. This new information is used to bring more light to the origin of this intriguing  
110 mineralization.

111

112

113

#### **SAMPLE DESCRIPTION AND METHODOLOGY**

114 The samples used for this investigation were collected in the 1980s by one of the authors  
115 (MT) from an abandoned core shed near the hole from which the ore body was removed. The  
116 studied samples, called NCH and NCN, originally formed part of the schistose outer rim of the  
117 Bon Accord Ni-oxide body (Tredoux et al. 1989; Tredoux et al. 2013). The samples are  
118 dominantly composed of nepouite and willemseite, after the olivine liebenbergite, with stringers  
119 and clumps of the Ni-spinel trevorite making up about 30% of the mineralogy (for explanations  
120 of the Ni-rich minerals in the Bon Accord Ni-oxide body, see de Waal 1972; 1978; 1979; de  
121 Waal and Calk 1973). As only a few hand specimens from Bon Accord Ni-oxide body are now  
122 available for study, only 830 grams of sample were used during the present investigation.

123 The material was crushed for 15 seconds with a swing mill, using a carbon steel bowl,  
124 and then sieved into the following fractions: +53 micrometers, <53 micrometers, 75 micrometers

125 and 106 micrometers. From these fractions, a heavy minerals concentrate was obtained at  
126 Barcelona University (Spain) using the HS 11 hydroseparator instrument and following the  
127 procedure recently described in several papers (Cabri et al. 2005a;b; Grammatikopoulos et al.  
128 2007; Rudashevsky et al. 2002; 2004). The concentrates were mounted in epoxy blocks and  
129 polished for mineralogical examination. Four polished blocks of one inch in diameter were  
130 obtained for each concentrate. The PGM and gold were located by scanning the polished blocks  
131 in part using the JEOL field emission electron microscope (FE-SEM) installed at the Barcelona  
132 University (Spain), and the JEOL JXA-8200 available at the Eugen F. Stumpfl Electron  
133 Microprobe Laboratory at the Leoben University (Austria). Selected PGM and gold grains with a  
134 size of more than five micrometers were analyzed quantitatively by the wavelength dispersive  
135 (WD) system at the Eugen F. Stumpfl Electron Microprobe Laboratory.

136 The gold minerals were analyzed using at 25kV accelerating voltage and 30nA beam current.  
137 The counting times for peak and background were 20 and 10 seconds for Au and Ag, and were  
138 increased up to 60 and 30 seconds in the analysis of trace elements. Under these conditions low  
139 detection limits were achieved for As (270 ppm), S (150 ppm), Fe (80 ppm), Co (70 ppm), Cu  
140 (120 ppm), Ni (100 ppm), Zn (140 ppm), Se (180 ppm), Sb (190 ppm), Bi (370 ppm), Hg (550  
141 ppm), and Te (80 ppm). Sulfur, Cu, Ni, Fe, Co and Zn were analyzed using the  $K\alpha$  lines, As, Ag,  
142 Se, Sb and Te using  $L\alpha$  and Au, Bi, Hg using  $M\alpha$ . The following analyzing crystals were used:  
143 TAP for As and Se, PETJ for S, Sb, Bi, Ag, Au and Hg, PETH for Te, and LIFH for Fe, Ni, Co,  
144 Zn and Cu. Natural, chalcopyrite, millerite, skutterudite, stibnite, calaverite, sphalerite, and  
145 synthetic electrum,  $CuSe$ ,  $Bi_2Te_3$  and  $Pd_3HgTe_3$  were used as reference material.

146 The quantitative analyses of PGM were performed using 20kV accelerating voltage and  
147 10nA beam current. The counting times for peak and background were 20 and 10 seconds,  
148 respectively. Pure metals were the reference material for Os, Ir, Ru, Rh, Pt and Pd. The natural  
149 minerals chalcopyrite, galena, and synthetic nickeline and  $Bi_2Te_3$  were used to calibrate Cu, Fe,  
150 S, Pb, Ni, As, Bi, and Te. The following X-ray lines were used:  $K\alpha$  for S, Fe, Cu and Ni;  $L\alpha$  for  
151 Ir, Ru, Rh, Pt, Pd, As and Te; and  $M\alpha$  for Os, Bi and Pb. The following diffracting crystals were  
152 selected: TAP for As, PETJ for S, Bi, Pb and Te, PETH for Ru, Os, Rh, LIFH for Ni, Cu, Ir and  
153 Pt.

154 Only qualitative EDS analyses could be performed for the PGM which has very small size  
155 (generally less than one micron), and in those case where they occur as minute intergrowth of

156 two or more phases.

157

158

159

## RESULTS

160 The precious minerals were encountered only in the +53 micrometers, <53 micrometers  
161 concentrates and they consist of PGM and electrum. The fractions 75 micrometers and 106  
162 micrometers proved to be barren. They occur as: i) minute inclusions (<3 micrometers) of  
163 various PGM in trevorite (Figs 2, 3), ii) large (5–70 micrometers) free grains of PGM and  
164 electrum liberated from the host phase (Figs 4, 5).

165 The grains included in trevorite may consist of a single phase (Fig. 3), or form composite  
166 aggregates of two or more PGM (Figs 2A, B, C, D, E). According to the EDS spectra, they  
167 comprise PGM compounds of Pd-Sb, Pd-Sb-As, Pd-Cu-Sb, Pt-Sb, Pt-As-S, Ru-As-S, Ru-S,  
168 along with several grains of Ni-Fe-As (Fig. 2F). Although their small size prevents any  
169 unequivocal mineralogical classification, the EDS data suggest possible attribution of the Pd-Sb  
170 PGM to the following ideal species: stibiopalladinite ( $\text{Pd}_5\text{Sb}_2$ ), naldrettite ( $\text{Pd}_2\text{Sb}$ ), ungavaite  
171 ( $\text{Pd}_4\text{Sb}_3$ ) and sudburyite (Pd,Sb). The Pt bearing PGM probably corresponded to genkinite  
172 ( $(\text{Pt,Pd})_4\text{Sb}_3$ ) or platarsite (PtAsS). The grains containing Ru and S very likely were laurite  
173 ( $\text{RuS}_2$ ) and ruarsite (RuAsS). The Ni-Fe compounds may correspond to one of the phases  
174 described by Tredoux et al. (2014, submitted).

175 Most of the free grains could be properly classified using electron microprobe  
176 quantitative analyses. They comprise electrum (Table 2) and the PGM sperrylite, PtAs<sub>2</sub> (Table  
177 3), sobolevskite, PdBi, and a Bi-rich kotulskite, PdTe (Table 4). Gold phases are very abundant  
178 in the concentrates NC-H and very rare in those obtained from the NC-N sample. Electrum  
179 usually occur as single-phase crystals varying in size from 5 up to 60 micrometers (Figs 4A, B,  
180 C) and only one grain was found associated with sperrylite (Figs 4E, F). The composition is  
181 almost homogenous with Ag concentrations between 26.64 and 29.11 wt% (Table 2). Among the  
182 trace elements analyzed in the gold grains, Co, Zn, Sb, As, Hg and Se are always below detection  
183 limit, and the contents of S, Ni and Te are very low (up to 0.07 wt%, 0.09 wt% and 0.08 wt%,  
184 respectively). Appreciable amounts of Fe (up to 0.71 wt%), Cu (up to 0.19 wt%), Bi (up to 0.49  
185 wt%) have been detected (Table 2).

186 Sperrylite was found to be particularly abundant in sample NC-H, mostly occurring as

187 single-phase grains of 10 to 70 micrometers in size (Figs 4A, B, C). Electron microprobe  
188 analyses show trace amounts of S, Os, Ir, Ru, Rh, Pt, and Pd. The sperrylite associated with gold  
189 (Figs 4E, F) is distinguished by slight higher Fe (2.49 wt%) and Rh (1.1 wt%) contents, while it  
190 is depleted in Os, Ir and Ru (below detection limit) (Table 3). Sobolevskite and the Pd-Te-Bi  
191 compound occur exclusively in the concentrates of the NC-N sample. They form single-phase  
192 crystals with sizes which vary from 5 to about 30 micrometers (Fig. 5). The Bon Accord  
193 sobolevskite appears to have rather pure composition PdBi with weak substitution of Fe up to  
194 9.67 at% (Table 4). On the basis of its composition of the Pd-Te-Bi mineral can classified as Bi-  
195 rich kotulskite, with 2.52 at% Fe. The two compositions are plotted on the ternary diagram Pd-  
196 Te-Bi (Fig. 6), and compared with phases of the sobolevskite-kotulskite solid solution, reported  
197 from various localities worldwide and compiled by Cook et al. (2002). The sobolevskite from  
198 Bon Accord roughly correspond to the PdBi end-member reported from Norilsk (Evstigneeva  
199 and Kovalenker 1975), whereas the Pd-Bi-Te has intermediate composition between PdBi and  
200 PdTe, compatible with experimental results (Vymazalova et al. 2013) and resembles PGM  
201 reported from Norilsk (Kovalenker et al. 1975), Two Duck Lake (Watkinson and Ohnenstetter  
202 1992), Lukkulaivaara (Groshovskaya et al. 1992) and Great Dyke (Coghill and Wilson 1993).  
203 This phase corresponds to a Bi-rich kotulskite.

204

205

206

## DISCUSSION

### 207 Relationships between mineralogy and geochemistry

208 The Bon Accord Ni-oxide body is characterized by anomalous concentrations of Ni, Sb  
209 (and to a lesser extent As) and by very low amount of S (Tredoux et al. 1989). Tredoux et al.  
210 (2014, submitted) have recognized, in the Bon Accord Ni-oxide body, a set of phases that  
211 possibly represent new minerals in the Ni-Sb-As system:  $\text{Ni}_3\text{Sb}$ ,  $\text{Ni}_5\text{Sb}_2$ ,  $\text{Ni}_7\text{Sb}_3$ ,  $\text{Ni}_{11}\text{Sb}_8$ ,  
212  $\text{Ni}_3(\text{As,Sb})$ ,  $\text{Ni}_5(\text{As,Sb})_2$  and  $\text{Ni}_7(\text{As,Sb})_3$ . Few Ni bearing sulfides have been also observed  
213 during this investigation. All these mineralogical observations are fully consistent with the  
214 geochemical signature of the Bon Accord Ni-oxide body.

215 The Bon Accord samples are also enriched in PGE, up to more than 7000 ppb of total  
216 PGE as reported by Tredoux et al. (1989) and in Table 1. The PGE total content of samples  
217 characterized by enrichment in trevorite vary from 6196 to 7692 ppb, whereas in those

218 characterized by the presence of abundant hydrous silicates the maximum concentration of PGE  
219 is 1012 ppb. Despite of the difference in the total PGE amount, all the analyzed samples are  
220 relatively depleted in IPGE (Os+Ir+Ru) especially in Os and Ir (Fig. 7). This is probably the  
221 explanation for why no Ir or Os species have been found. Among the PPGE (Rh+Pt+Pd),  
222 although Rh shows enriched chondrite normalized values, it must be borne in mind that Rh, in  
223 absolute terms, is by far the rarest of the PGE, which would explain why no Rh phases were  
224 found either.

225 The identification of native Ru associated with minerals of the Ni-Sb-As system (Fig. 1)  
226 does not account for reported whole-rock PGE abundance. Failure in finding a PGM assemblage  
227 consistent with geochemical data was probably caused by the uneven distribution of the PGM  
228 grains throughout the sample, which has as a consequence the fact that there is little chance to  
229 detect them in polished sections. Application of the hydroseparation technique has proved that  
230 the PGM are relatively abundant and include specific minerals of all the PGE, except Rh, Os and  
231 Ir. Furthermore, the occurrence of electrum accounts for the relatively high Au content in bulk  
232 rock amounting up to more than 300 ppb in samples of the trevorite-rich assemblage from the  
233 undeformed core of the body (Tredoux et al. 1989).

234

### 235 **Origin of the PGM-Au assemblage**

236 We note that the minute PGM and associated Ni-Fe-Sb-As inclusions in trevorite are not  
237 associated with fissures, fractures or crystal faces of the spinel phase. They rather appear as tiny,  
238 solid drops incorporated in trevorite, analogous to the primary magmatic PGM inclusions  
239 captured by chrome spinels crystallizing from mafic melts. Trevorite is known to be part of the  
240 secondary mineral assemblage together with nepouite and possibly formed during the main  
241 serpentinization event, coincident with exposure of the Bon Accord Ni-oxide body to near-  
242 surface hydrothermal conditions, but predating the last stage of schistosity (Tredoux et al. 1989).  
243 In this view, we can assume that all the PGM inclusions (Pd-Sb, Pd-Cu-Sb, Pd-Sb-As, Ru-S, and  
244 Pt-As-S) and the other Ni-Fe-Sb-As compounds, were present in the system at the time of  
245 trevorite crystallization. Their composition, comprising metal compounds of Sb and As, and  
246 above all their morphology and textural relationships do not support that these grains are  
247 remnants of primary minerals incorporated in secondary Ni oxide. More likely they precipitated  
248 in equilibrium with the hydrothermal conditions that generated the trevorite-nepouite secondary

249 assemblage.

250 The origin of the PGM and electrum encountered in the concentrates as free grains is  
251 more difficult to be interpreted given the lack of any textural evidence. If the free grains of PGM  
252 and electrum are remnants of primary phases, then their paragenetic assemblage should fit one of  
253 the models proposed for the origin of the Bon Accord Ni-oxide body, and critically overviewed  
254 in Tredoux et al. (1989).

255 An extraterrestrial origin has been discarded based on many geochemical inconsistencies,  
256 including siderophile element ratios, and more recently by Cr isotopic data (Tredoux et al. 2013).  
257 An impact hypothesis may find some support in the recent discovery of nano-particles of PGE  
258 included in chondritic microspherules from deep-sea sediments of the Indian Ocean  
259 (Rudraswami et al. 2011) and the Paraburdoo-Reivilo Archaen layers of Western Australia and  
260 South Africa (Goderis et al. 2013). However, the markedly negative slope of the PGE chondritic  
261 patterns (high IPGE/PPGE ratio) with over-chondrite Ir and Os contents in the Indian Ocean  
262 micronuggets (Rudraswami et al. 2011), as well as the Rh-Pt-Pd-Au negative segment in the  
263 Archaen-layers microspherules (Goderis et al. 2013) are at odds with the Bon Accord occurrence  
264 (Fig. 7), as it is the systematic absence of Au phases in these astrobleme materials.

265 The PGM-Au mineral assemblage of Bon Accord neither supports a derivation from  
266 ophiolite-plutonic rocks (strongly residual mantle or podiform chromitites) in which IPGE  
267 predominate, and PPGE fractionation is strictly related with the presence of sulfides of magmatic  
268 or hydrothermal origin (Naldrett and Von Gruenewaldt 1989). The PGE chondrite-normalized  
269 patterns may recall those of several Ni-sulfide ores associated with mafic-ultramafic rocks. In  
270 particular, PGM members of the sobolevskite-kotulskite series and/or the uncommon association  
271 gold-sperrylite have been previously described from Norilsk (Evstigneeva and Kovalenker  
272 1975), Talnотry (Power et al. 2004), Sudbury (Ames et al. 2007), and the Ivrea Zone (Garuti and  
273 Rinaldi 1986; Zaccarini et al. 2014). A number of Pt-Pd-Sb-As-Bi-Te PGM have been reported  
274 from nicheliferous sulfide deposits associated with komatiite such as Kambalda (Hudson 1986;  
275 Godel et al. 2012) and even from the low-sulfide PGE mineralization of Kevitsa (Kaukonen  
276 2010) and Lukkulaisvaara (Groshovskaya et al. 1992). If the free-grains of PGM and electrum  
277 are remnants of a primary assemblage, Bon Accord might be the strongly metamorphosed  
278 equivalent of a small, low-sulfide mineralization enriched in PGE and Au. However, this model  
279 is undermined by several field and geochemical contrary evidences (Tredoux et al. 1989).

280 Finally, the PGM mineralogy of Bon Accord has some features in common with  
281 micronuggets encountered in orogenic lherzolite possibly exhumed from sub-continental  
282 environments (Garuti et al. 1984; Lorand et al. 2010). The PGE distribution is rather  
283 unfractionated (low Pd/Ir ratio) with some Pd-Au enrichment in mantle massifs associated with  
284 deep granulitic crust (i.e. Ronda and Ivrea Zone, Crocket 2002). The PGM assemblage appears  
285 to be partly residual (Pt-Ir-Os alloys) having survived partial melting, and partly metasomatic  
286 (IPGE-Sb-Bi-Te compounds) being a result of mantle refertilization by reaction with percolating  
287 basaltic melts, or reworking under low-temperature hydrothermal conditions. However, mantle  
288 lherzolite, because of their fertile character, do not display the over-abundance of Ni observed in  
289 the Bon Accord samples that would be more consistent with material proceeding from the deep-  
290 mantle/core transition or the core itself.

291 As an alternative, we may speculate that the most likely textural position of the PGM and  
292 electrum, before liberation, was inside the nepouite matrix, together with the abundant Ni-As and  
293 Ni-Sb compounds described from Bon Accord (Tredoux et al. 2014, submitted). In this case, the  
294 entire mineral assemblage may have a common secondary origin, having been formed during the  
295 hydrothermal reworking of the Bon Accord Ni-oxide body. In a number of natural occurrences,  
296 precipitation of PGE-Sb-As-Bi-Te compounds together with PGE alloys, PGE oxides, may  
297 results from the low-sulfidation regime that usually accompanies hydrothermally driven  
298 serpentinization of mafic-ultramafic bodies.

299 The ligands in the newly formed PGM (As, Sb, Bi, Te, O) may be already present in the  
300 primary system but, more frequently, they proceed from the same source of the hydrothermal  
301 solutions. This has been reported from young and ancient ophiolite complexes and layered  
302 intrusions elsewhere in the world (Garuti and Zaccarini 1997; Zaccarini et al. 2005; 2006; Garuti  
303 et al. 2007; 2012; Tsoupas and Economou-Eliopoulos 2008; Proenza et al. 2008). In this model,  
304 the metals Ni-PGE-Au were original components of the primary mineral assemblage of the Bon  
305 Accord precursor, whereas As, Sb, Bi, Te, O might have been contributed by the metasomatizing  
306 fluids, during near-surface evolution of the ore body.

307

308

309

### IMPLICATIONS

310 A major implication of this study is that the mineralogical investigation of very small and

311 dispersed phases, like PGM, needs to combine different techniques. This is particularly required  
312 when results of simple *in situ* mineralogical analyses do not predict bulk-rock PGE contents in a  
313 sample. Our *in situ* mineralogical study on polished sections provides satisfactory data on the  
314 distribution and composition of very small PGM grains included in larger mineral host.  
315 However, interception of rare, large grains in polished sections has an unlikely chance of  
316 success. Therefore, large PGM may be poorly represented, although accounting for a big  
317 proportion of the total PGE amount in the sample. Mineralogical analyses based on separation of  
318 PGM from the matrix are unable to efficiently concentrate phases less than 5 micrometers in  
319 size, but allow treatment of a larger volume of samples, thus improving the possibility to  
320 encounter dispersed phases (Cabri et al. 2005a,b; Grammatikopoulos et al. 2007; Rudashevsky et  
321 al. 2002; 2004; Oberthür et al. 2008; Cabri 2012). As a consequence, the hydroseparation is a key  
322 technique enabling the study of very small and dispersed minerals. Therefore, the PGM should  
323 be investigated using both these complementary analytical methodologies to achieve more  
324 reliable and complete results.

325 In conclusion, the study of heavy-mineral concentrates from the Bon Accord Ni-oxide  
326 body has shown the existence of a complex PGM-Au mineral assemblage. The mineralogy is in  
327 good agreement with results of the PGE and Au analysis. There is convincing evidence that the  
328 PGM-Au minerals are of secondary origin, probably generated during low-temperature  
329 metamorphism of the ore body. The results of this study, although not conclusive, have  
330 contributed to cover an important lack of knowledge about the mineral residence of Pd, Pt, and  
331 Au in the Bon Accord Ni-oxide body.

332

### 333 **ACKNOWLEDGMENTS**

334 Justine Magson of the Geology Department of the University of the Free State is thanked for crushing and  
335 sieving the sample in preparation for hydroseparation. The University Centrum of Applied Geosciences of Austria  
336 (UCAG) is acknowledged for making available the facilities of the Eugen F. Stumpfl Microprobe Laboratory.  
337 Keith D. Putirka and Alejandro Fernandez-Martinez are gratefully thanked for their editorial review. This  
338 manuscript benefited from the constructive comments of Louis J. Cabri and Nigel Cook. Their very useful  
339 suggestions greatly improved the scientific quality of this manuscript.

592 **Captions to figures.**

593

594 **FIGURE 1.** BSE image of ruthenium associated with a  $\text{Ni}_7(\text{As,Sb})$ , trevorite and cloroapatite and  
595 included in a Ni-rich silicate, found during the *in situ* investigation of Bon Accord polished and  
596 thin sections.

597

598 **FIGURE 2.** FE-SEM images of poly-phase PGM and Fe-Ni-As phase included in trevorite, found  
599 in the concentrates of Bon Accord. A = large view. B = bi-phase grain composed of a Pd-Sb-As  
600 and Pd-Sb compounds. C = = bi-phase grain composed of a Pd-Cu-Sb and Pd-Sb. D, E =

601 complex PGM of Ru-S, Fe-Ni-Sb and Pt-Sb. F = single phase of Fe-Ni-As.

602

603 **FIGURE 3.** FE-SEM images of single phase PGM found in the concentrates. A = Ru-S  
604 compound. B, C and D = grains composed of Pd-Sb.

605

606 **FIGURE 4.** FE-SEM images of free PGM and gold found in the heavy mineral concentrates of  
607 Bon Accord. A, B and C = sperrylite single phase. D = Electrum single phase. E = Bi-phase  
608 grain composed of sperrylite and electrum. F = enlargement of the grain shown in E.

609

610 **FIGURE 5.** BSE images of free grains of sobolevskite (A, B) and a Pd-Te-Bi compound (C)  
611 found in the Bon Accord heavy mineral concentrate.

612

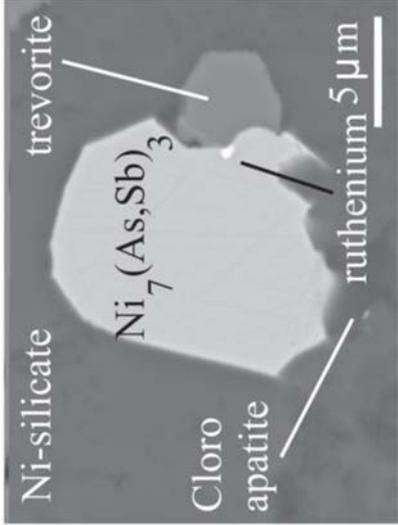

613 **FIGURE 6.** Composition (At%) of PGM from Bon Accord (black square) plotted in the Pd-Bi-Sb  
614 ternary diagram, compared with that from other localities. Grey circle = Norilsk (Kovalenker et  
615 al. 1975; Evstigneva and Kovalenker 1976), white circle = Lukkulaivaara (Groshovskaya et al.  
616 1992), black circle = Two Duck Lake (Watkinson and Ohnenstetter 1992), grey square = Great  
617 Dyke (Coghill and Wilson 1993). Compositional fields after Cook et al. (2002).

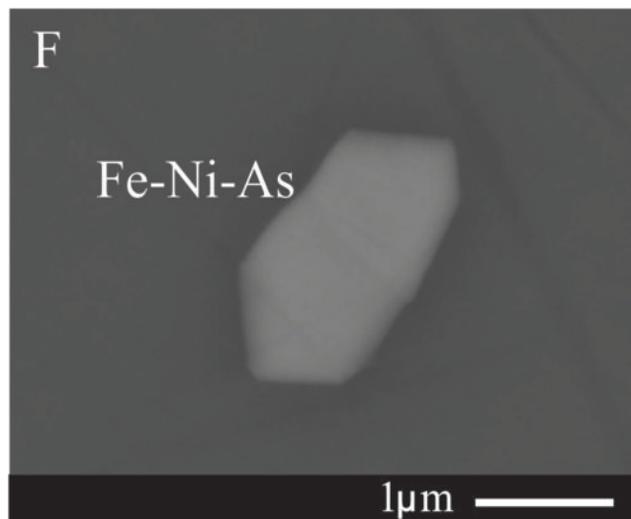

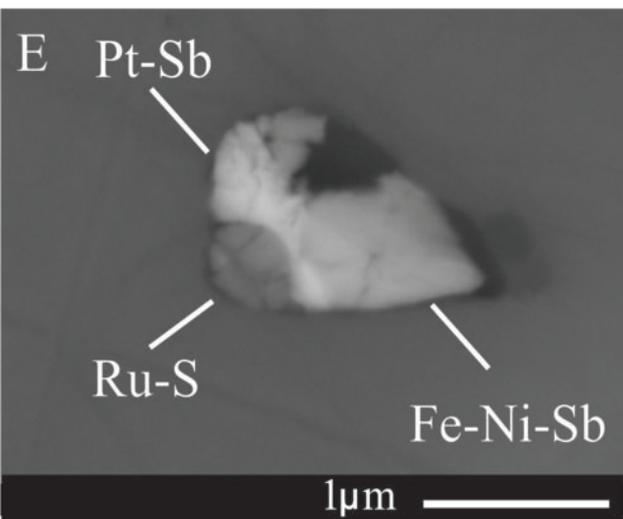

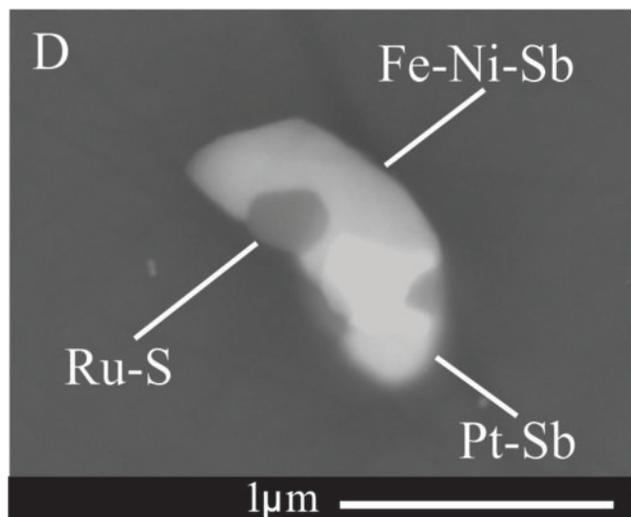

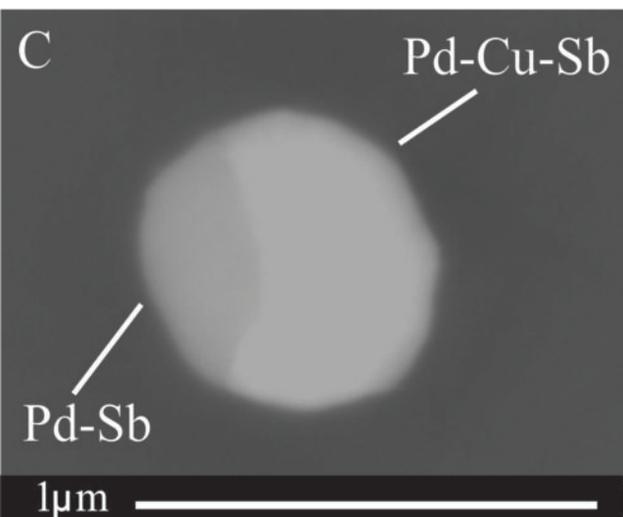

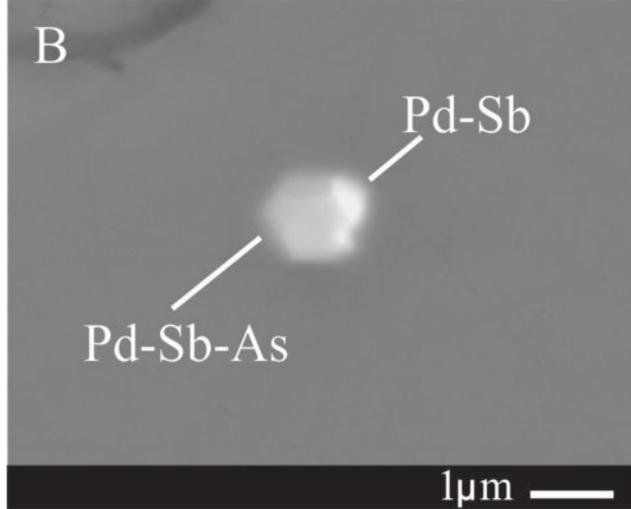

618

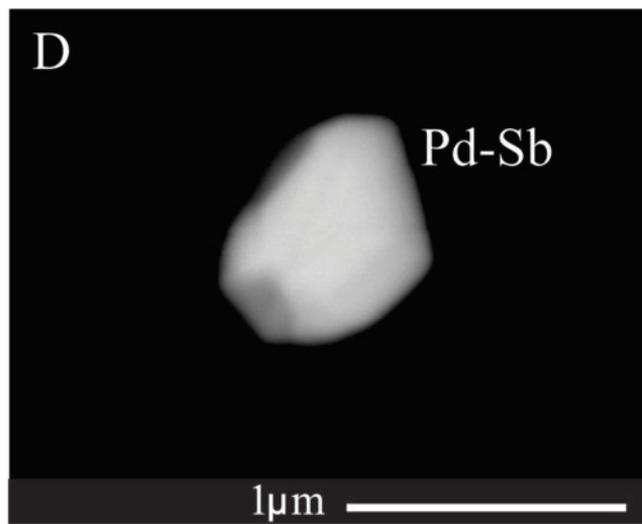

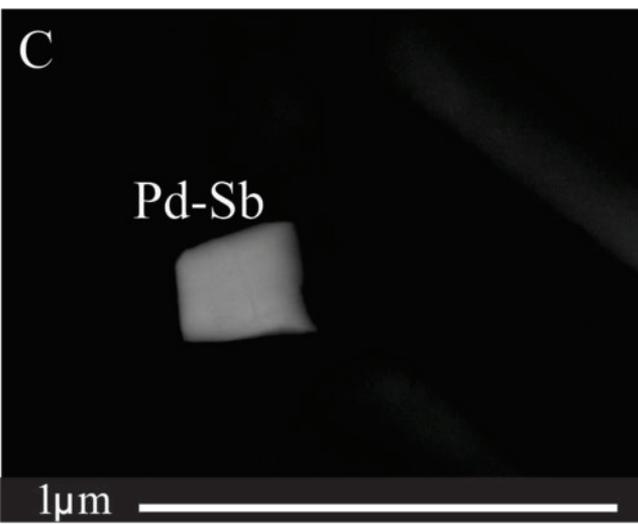

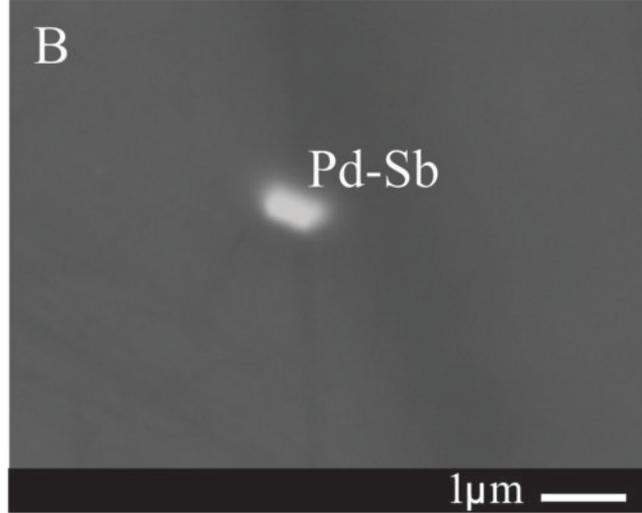

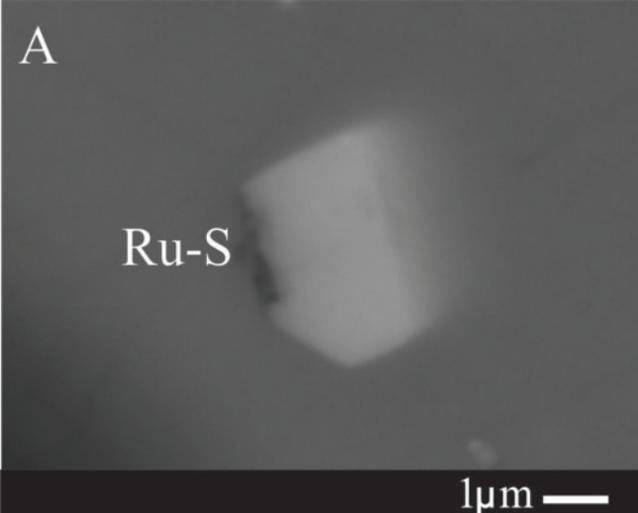

619 **FIGURE 7.** PGE and Au chondrite-normalized (Naldrett and Duke 1980) patterns of the Bon  
620 Accord samples (data from Tredoux et al. 1989).
