8 **Abstract**

9 The accumulation of metals and metalloids in diagenetic pyrite framboids is of interest

10 because framboids can be a sink for heavy metal contaminants, a source of metals in ore

11 deposits, and a tool to interpret paleo-ocean chemistry. In this study we have used laser

12 ablation inductively coupled plasma mass spectrometry (LA-ICPMS) to analyze pyrite

13 framboids from both the contaminated Derwent Estuary and the uncontaminated Huon

14 Estuary in Tasmania, Australia. While the enrichment of many trace metals in the Huon

15 Estuary followed expected trends, the trends in the Derwent were quite different. In addition

16 to the expected high contents of Pb, Zn and Cu in the contaminated interval it was found that

17 a number of elements are incorporated into pyrite less within the contaminated zone. It is

18 suggested that this is due to over competition for adsorption sites on the growing iron sulfides

19 in the contaminated zone resulting in diffusion of several elements down. This results in an

20 increase of these elements in pyrite below the zone of major contamination. The LA-ICPMS

21 technique also provided the opportunity to obtain accurate data on gold, silver and tellurium

22 in diagenetic pyrite, something rarely achieved in sequential leach extractions due to the low

23 concentrations of these metals observed in nature.

25   Diagenetic, pyrite, trace metals, framboid, metal contamination, LA-ICPMS

26   **Introduction**

27   Metal and metalloid accumulation in sediments has recently become of interest for three main

28   reasons. Firstly, pyrite framboids can be important sinks for metals and metalloids (such as

29   As) in contaminated rivers and estuaries (Lowers et al., 2007). Secondly, trace metal

30   contents of shale can be used to interpret paleo-environmental conditions (Algeo, 2004;

31   Anbar et al., 2007; Berner et al., 2013; Tribovillard et al., 2006) and since diagenetic pyrite is

32   one of the sinks for trace metals in sediments (Dellwig et al., 2002; Huerta-Diaz and Morse,

33   1992; Neumann et al., 2013), the processes that led to enrichment of trace metals in pyrite are

34   important. Thirdly, recent ore deposit models suggest that diagenetic pyrite is the source for

35   several significant gold deposits (Large et al., 2007, 2009; Thomas et al., 2011). It is

36   therefore important to gain some understanding of the factors that control the uptake of trace

37   elements in pyrite. Previous studies have used partial digestions (Huerta-Diaz and Morse,

38   1992) to establish the variations of metal content in diagenetic pyrite according to sediment

39   depth. While this is a useful technique for studying at uncontaminated sediments, there are

40   many potential problems including the specificity of the reagents (Martin et al., 1987). This

41   is of particular concern in contaminated estuaries where there may be other metal bearing

42   sulfides (e.g. sphalerite, chalcopyrite, and galena) which dissolve under similar conditions to

43   pyrite.

44   This study examines pyrite samples from a metal-enriched site in the Derwent Estuary in

45   Tasmania and compares them to the pyrite formed in an uncontaminated environment in the

46   Huon Estuary some 45 km to the south to determine relative affinities of different trace

47   metals for incorporation in framboidal pyrite. To avoid problems associated with specificity

48   of reagents in partial digestion chemical analyses we employ LA-ICPMS analyses to directly

49   determine the composition of trace metals in pyrite. To achieve similar results synchrotron

50   μ-XRF has been used to analyze trace element content of pyrite (Berner et al., 2006;

51   Neumann et al., 2013). While synchrotron μ-XRF is preferable due to its superior detection

52   limits and spatial resolution we show in this paper that LA-ICPMS is a useful technique

53   provided that the framboids analysed are large enough to obtain an adequate signal.

54   **Trace element incorporation into diagenetic pyrite**

55   The iron sulfides examined in this study are pyrite framboids, which are clusters (often

56   spherical) of microcrystalline pyrite rarely over 15μm in diameter (Figure 1). These crystals

57   form throughout the world in sediments under anoxic to euxinic conditions. The mechanism

58   of framboid formation has been the subject of much research and debate (Schoonen, 2004).

59   The process begins with the formation of iron monosulfides, which have a much higher rate

60   of nucleation, effectively prohibiting the direct precipitation of pyrite unless seed crystals of

61   pyrite are present (Schoonen and Barnes, 1991). These iron monosulfides are then converted

62   to the more thermodynamically stable pyrite (Rickard and Luther, 1997). A common FeS

63   species used in experimental studies is mackinawite (FeS_m) (Lennie et al., 1995; Wolthers et

64   al., 2003). However, FeS_m may not be a necessary precursor in many natural systems and is

65   only observed in systems with high Fe concentrations (Rickard and Luther, 2007), though as

66   the system examined in this study has a significant Fe supply (Risdon Zn smelter) FeS_m was

67   probably present at one stage. The conversion of FeS to FeS_2 can be enhanced by the

68   presence of sulphur species with oxidation states between SO_4^{2-} and H_2S^{2-} which can be

69   common near the reduced sediment / oxidized water column interface (Neumann et al.,

70   2005).

4

71   Bacteria can play a role in converting organic sulfur compounds to reactants that can take

72   part in pyrite formation (Donald and Southam, 1999; Schoonen, 2004). Microorganisms can

73   also provide anionic sites on their cell walls that are capable of binding ferric iron (Donald

74   and Southam, 1999; Konhauser, 1998). These ferric iron binding sites promote the growth of

75   a thin FeS film on the outside of the cell wall (Schoonen, 2004), which then can react to form

76   pyrite. Pyrite precipitation may also be enhanced by the presence of an active surface that

77   allows Fe^{2+} to react with $S_2(-II)$ to form pyrite. Other Fe sulfides (such as mackinawite)

78   and/or organic surfaces may also fulfill this role (Rickard and Luther, 2007).

79   The mechanisms for the incorporation of trace metals into pyrite framboids are still not fully

80   understood. Work by Morse and Arakaki (1993) showed that many trace metals can be

81   adsorbed and incorporated into the precursor FeS mineral, mackinawite. They showed that a

82   metal with a sulfide species that has a higher solubility than mackinawite would have a

83   similar surface affinity to mackinawite and a metal with a sulfide species with lower

84   solubility than mackinawite would have a higher surface affinity with decreasing metal

85   sulfide solubility. Renock et al. (2009) showed that the mechanism of arsenic precipitation

86   onto mackinawite differs based on the pH of the solution. Arsenic forms "realgar like" As

87   sulfide minerals on the surface of mackinawite at pH 5 but at pH 9 it instead forms a coating

88   of arsenic on the surface of the mackinawite, possibly due to adsorption of As oxyanions

89   (Renock et al., 2009). However, mackinawite is not a long lived species and reaction

90   pathways to convert mackinawite to pyrite proposed by (Rickard and Luther, 1997) require

91   its dissolution, which would likely release some of the trace metals. Work by Huerta-Diaz

92   and Morse (1992) showed that as progressively more mackinawite is converted to pyrite a

93   greater concentration of transition metals (excluding Cr) are incorporated into the structure of

94   pyrite. This process is limited only by the amount of pyrite produced and the amount of trace

95   metals available to be added to the pyrite. They also found that, although metals such as Cr,

96 Zn, Pb and Cd do exhibit increases as more of the reactive iron is converted into pyrite (i.e.

97 with increasing degree of pyritization), the increases are not as significant as with the other

98 transition metals. This may be because these elements are not held within the structure of the

99 pyrite.

100 Based on their study of the Lower Toarcian Posidonia Shale, Berner et al. (2013) separated

101 trace elements in pyrite into four groups: heavy metals (Cu, Ni, Co, Pb, Bi and Tl);

102 oxyanionic elements (As, Mo and Sb); elements that are predominantly in sub-microscopic

103 sphalerite inclusions (Zn and Cd) and elements that occur in micro-inclusions of organic

104 matter or silicates (Ga and V). Berner et al. (2013) and Dellwig et al.(2002) have shown that

105 heavy metals tend to be incorporated in pyrite predominantly during diagenesis of anoxic

106 sediments. This occurs by a number of different processes: co-precipitation; chemical or

107 physical adsorption and redox reactions between dissolved species and the pyrite surface or

108 the surface of pyrite precursors.

109   In this study LA-ICPMS was used to analyze individual pyrite framboids and determine their

110 trace metal and metalloid abundance. This is an improvement over sequential extraction

111 techniques of analyzing pyrite as it does not have the problems of selectivity of reactants that

112 were identified by Martin et al. (1987). By avoiding the problem of selectivity of reactants it

113 was possible to examine pyrite framboids that were growing in an area that contains high

114 levels of several trace elements to examine how trace elements are incorporated into

115 diagenetic pyrite. This is the first study to analyze the accumulation of elements in pyrite

116 framboids from a heavily contaminated site and gives insight into the importance of

117 competition for adsorptive sites on the surface of growing pyrite grains for the incorporation

118 of metals within diagenetic pyrite.

119   **Material and Methods**

Location and setting

121   Samples were taken from two estuaries in southern Tasmania, Australia. A sediment core

122   from the Derwent Estuary, (Figure 2) (Gregory et al., 2013) was taken from Prince of Wales

123   Bay, adjacent to the Risdon zinc refinery which has been operating since 1917. Prior to the

124   1970's little environmental precautions were taken; smelter waste was deposited directly into

125   the estuary and ore particles were blown into the water from uncovered stockpiles on the

126   river bank (Gregory et al., 2013). In 2010 the Australian national pollution inventory

127   reported 99 kg As, 311 kg Cd, 299 kg Cu, 654 kg Pb and 23834 kg Zn were deposited into

128   the estuary (Milne, 2012).

129   The Huon Estuary is located approximately south-southwest of the Derwent Estuary at 43°

130   14' S and 147° 4' E. The Huon Estuary has similar underlying geology to the Derwent and

131   drains a hinterland of mixed forest and farming areas. In comparison to the Derwent the

132   Huon Estuary is sparsely populated and hosts few major industries on its margins and is

133   therefore a low contamination analogue of the Derwent Estuary (Jones et al., 2003).

Sample collection and preparation

135   A 1.05 m sediment core taken from Prince of Wales bay (42°49'33"S, 147°18'12"E) in

136   August 2010 and a 0.65 m long sediment core taken from the Huon Estuary (43°10'26"S,

137   146°59'7"E) in December 2011 were both sampled using an Uwitec hammer corer (Figure

138   2). The black silt found in both cores (predominantly 2.5Y 2.5/1 with zones of 5Y 2.5/1 on

139   the Munsell colour chart) contained nearly no stratification and exhibited strong evidence of

140   bioturbation by worms and arthropods. The sediment was extruded by pushing a plunger

141   through the tube and samples were taken every 2.5 cm for the first 30 cm of the Derwent

142   sediment core and 5 cm for the remainder of the cores. One half of each sample was dried

143   prior to processing for geochemical analysis; one quarter was removed for heavy mineral

144   separation while the remaining quarter was stored in a freezer for future use. Heavy minerals

145   were separated by either panning or by heavy liquid separation (heavy liquid separation was

146   only used for the Derwent samples). The samples were first panned using a plastic riffled

147   pan. The concentrate was then transferred to a watch glass which was further panned to

148   produce a concentrated separate of heavy minerals. Individual pyrite framboids were

149   removed from the concentrate using a steel needle. Framboids were then mounted in 2.5 cm

150   diameter epoxy mounts prior to LA-ICPMS analysis. Heavy mineral separates were also

151   made by mixing the sediment sample with lithium heteropolytungstates in a separatory funnel

152   and leaving for 24 hrs. The dense minerals (>2.95 specific gravity) settled to the bottom of

153   the funnel where they were collected by opening the valve and draining the bottom fraction

154   of the lithium heteropolytungstates with the dense minerals. The minerals were filtered out

155   and washed three times with deionized water. This concentrate was mounted in epoxy for

156   LA-ICPMS analysis. The extracted framboids tended to be 10-20 µm in diameter and were

157   usually spherical. However pyrite was also found to replace/fill biological structures and take

158   the shape of that structure, an partially filled example of this is shown in Figure 1A.

159   **Analytical methods**

160   The dried samples were ground to <63 µm using a chromium steel mill. These samples were

161   analyzed for metal concentrations using a combination of ICPAES (Agilent 725 Radial

162   ICPAES) and ICPMS (Perkin Elmer Elan 9000 ICPMS) techniques at ALS Chemex in

163   Brisbane, Australia and separately for gold using the instrumental neutron activation (INAA)

164   technique at the Ecole Polytechnique Montreal in Canada. At ALS Chemex's lab the

165   samples were digested by four acids (HCl, HNO_3, H_2SO_4 and HF) prior to being analyzed by

166   ICPAES and ICPMS. Only ICPAES analysed Al, Ca, Cr Fe, K, Mg, Mn, Na, P, S, V and Zn

167   while only ICPMS analysed Ce, Cs, Ge, Hf, In, Li, Nb, Rb, Re, Sn, Ta, Te, Th and Y. Both

168   methods analysed Ag, As, Ba, Be, Bi, Cd, Co, Cu, Ga, La, Mo, Ni, Pb, Sb, Se, Sr, Ti, Tl, U,

169   W and Zr and the final values were obtained by merging the results from both methods using

170   a complex algorithm (details provide in electronic appendix). Blanks, geochemical reference

171   materials (MRGeo02 and GBM398-1; prepared by Ore Research & Exploration Pty Ltd and

172   Geostats Pty Ltd respectively) and sample duplicates were used to ensure quality control.

173   These were within the criteria for acceptable values (10-20% of the expected values, with

174   higher variation considered acceptable for elements with low expected values). Details of the

175   Derwent samples have been reported in a companion study (Gregory et al., 2013). At the

176   Ecole Polytechnique the samples were placed into 7 ml irradiation polyethylene vials prior to

177   irradiation in the Slowpoke nuclear reactor, where they were irradiated for 30 min at an

178   average neutron flux of 5 x 10^{11}/cm^2/s (varying from 4.43 to 5.58 x 10^{11}/cm^2/s as a function

179   of sample position in the irradiation site). They were then allowed to decay between three

180   and five days before the gamma ray spectrum was recorded for three to five hours at a

181   distance of 1.6 mm. The amount of gold was then calculated using EPAA v3.0 (Ecole

182   Polytechnique Activation Analysis) software. Over several years of analyses the reactor

183   neutron flux and detector efficiency has been reproducible to 1% and a quality control

184   standard containing 30 µg gold is routinely analyzed and it was within 5% of the expected

185   value.

186   Analyses of available metal ions for four of the Derwent samples were conducted as part of

187   the companion study based on the methods proposed by Zeien and Brümmer (1989). This

188   method consisted of seven leach steps designed to release metals that are: easily exchanged,

189   weakly complexed and bound by carbonates, bound by Mn (hydr)oxides, bound by organic

190   matter, bound by Fe (hydr)oxides of low crystallinity, bound by Fe (hydr)oxides of high

191   crystallinity and the residual fraction. Of these the first four leachates have been presented in

192   this study as possibly available for incorporation into pyrite. Though it should be noted that

193   some of the elements held within the Mn (hydr)oxides and organic matter may be unavailable

194   for incorporation into pyrite because they are too strongly held by the organic matter. The

195   first four leachates were obtained by leaching the samples with: 1 M NH_4NO_3 for 24 hours at

196   20°C (leach 1); 1 M NH_4OAc (pH 6) for 24 hours at 20°C (leach 2); 0.1 M NH_3OHCl +

197   NH_4OAc (pH 6) for 0.5 hours at 20°C (leach 3) and 0.025 M NH_4-EDTA (pH 4.6) for 1.5

198   hours at 20°C (leach 4) (Gregory et al., 2013). The resulting aliquots were analyzed in the

199   Central Science Laboratory at the University of Tasmania using an ELEMENT 2 sector field

200   ICP-MS (Thermo Fisher, Bremen, Germany). Quality control was undertaken by analyzing

201   calibration solutions as 'unknowns' to monitor instrument performance and by analyzing a

202   water standard (NIST_RefWater1640a) to verify calibration accuracy.

203   The metal and metalloid contents of pyrite framboids were determined using a LA-ICPMS

204   system (a New Wave UP-193SS Nd:YAG Q-switched Laser Ablation System or a New

205   Wave UP-213 Nd:YAG Q-switched Laser Ablation System coupled to an Agilent 7500a

206   Quadrapole ICP-MS) based at the ARC Centre of Excellence in Ore Deposits at the

207   University of Tasmania. Using a 10 µm beam the samples were ablated in an ultra-high

208   purity He atmosphere before being mixed with Ar and flowing into the ICPMS. Laser energy

209   of 1.8 to 2.5 Jcm^{-2} (for the New Wave UP-193ss) and approximately 3.5 J/cm^2 (for the New

210   Wave UP-213) were used for all analyses while the repetition rate was 5 Hz. Data was

211   collected over 70-90 s intervals, with a 30 s pre-ablation acquisition (background) interval

212   and a 40-60 s acquisition interval. Generally the first 20 s of the laser signal was used for

213   data reduction due to the tendency for the laser to completely ablate through the pyrite

214   framboid. However, this was enough time to obtain sufficient signal to produce analyses

215   with adequate detection limits and errors for most elements. Many of these results had

216   relatively high detection limits for Au and Te (>0.1 ppm and >1.0 ppm respectively) and so

217   an additional 97 samples were analyzed for a limited number of elements (Au and Te) in an

218   attempt to lower the detection limits.

219   The primary standard used to calculate concentrations and correct for instrument drift was

220   STDGL2b-2. The standard is a lithium-borate fused disc of pyrite and sphalerite powder

221   doped with certified element solutions (Danyushevsky et al., 2011). This standard yields an

222   error of less than 15% for most elements. The standards were analyzed twice at the

223   beginning and end of each session, before and after each sample change and every one to two

224   hours of analysis time. A total of 256 analyses were conducted. Iron was used as an internal

225   standard as pyrite rarely varies from its stoichiometric value by more than 5%

226   (Danyushevsky et al., 2011).   All results were corrected for linear drift and data reduction

227   was undertaken following the methodology developed by Longerich et al. (1996) using

228   SILLS software (Guillong et al., 2008).

229   **Results**

230   **Geochemistry**

231   Results for the whole sediment analysis are summarized in Figure 3. A more comprehensive

232   analysis of the bulk chemistry of the sediments is presented in a companion paper (Gregory et

233   al., 2013). It is readily apparent that the Derwent samples are much more enriched than the

234   Huon samples above 75 cm depth for all reported elements except Co, Te and Mo (Figure 3).

235   The increase in S content with depth in the Huon samples may reflect a natural increase in the

236   degree of pyritization in the core (i.e. the amount of reactive Fe that has been precipitated as

237   pyrite) (Figure 3). The Derwent core sample has been divided into 5 different groups based

238   on the geochemical results: moderate metal and low sulfur (0 to 25 cm); moderate metal and

239   high sulfur (25 to 45 cm); high metal (45 to 55 cm); high to low metal transition zone (55 to

240   80 cm) and low metal (80 to 100 cm). Representative samples from four of these groups

241   were analyzed by sequential analysis to determine what sediment components the different

242   metals are held within (Gregory et al., 2013). Results for the amount of trace metals that may

243 be available for incorporation into pyrite are summarized in Table 1. These are the sum of

244 the easily extractable fraction; carbonate held fraction; Mn(hydr)oxide fractions and organic

245 held fraction. The poorly crystallized Fe (hydr)oxide and well crystallized Fe (hydr)oxide

246 fractions obtained from the sequential leach extractions were not included because in the

247 Derwent Estuary there is a high concentration of franklinite (zinc ferrite) which dissolves

248 under the conditions used to extract the different Fe (hydr)oxide fractions (Gregory et al.,

249 2013). This franklinite is stable in the sediments as is indicated by SEM analyses that show

250 no alteration on the rims of the grains (Gregory et al., 2013). Thus it was believed that

251 including analyses from these extractions would give concentrations much higher than those

252 actually available for incorporation in the pyrite. Unfortunately degree of pyritization

253 analyses are not possible in the Derwent Estuary due to the presence of significant quantities

254 of Fe (hydr)oxide and sulfide minerals being introduced into the estuary as smelting by

255 products (Gregory et al., 2013). For complete discussion on techniques used to isolate these

256 different fractions please see Gregory et al. (2013).

257 During the course of this study 159 pyrite framboids were analyzed for Al, V, Co, Ni, Cu, Zn,

258 As, Mo, Ag, Cd, Te, Au, Pb and Bi and 97 pyrite framboids were analyzed for only Au and

259 Te using the LA-ICPMS technique. Median, maximum and minimum values for Zn, Pb, Cu,

260 Bi, Ni, Co, Mo, As, Au, Ag and Te in pyrite for the Derwent and Huon Estuaries are reported

261 in Table 2 and 3 respectively.

262 Median values for pyrite framboids from the Huon Estuary are generally uniform with

263 concentrations of trace metals varying little with depth. Gold, Ag and Te from individual

264 grains are generally below detection limits and medians of Zn (26 – 65 ppm), Pb (0.30 – 2.5

265 ppm), Bi (0.05 – 12 ppm), Ni (2.77 – 18.8 ppm), Co (0.87 – 25.7 ppm) and As (122 – 590

266 ppm) show little systematic variation with depth. Whereas the concentration in pyrite of Cu

12

267   (11 – 82 ppm) and Mo (below 30 cm depth) (5.3 – 40 ppm) show a significant increase with

268   increasing depth (Figure 4).

269   The Zn, Pb, Cu and Bi content in pyrite framboids in the Derwent follow the trend indicated

270   by the whole rock analyses (Figure 4), with the highest amount of metal in the framboids

271   occurring in the most contaminated zone but with much lower content of metal within the

272   pyrite than in the sediment itself. Arsenic in pyrite also follows the whole rock values;

273   however it contains higher As values than the sediment. The concentration of Ag in pyrite is

274   relatively low and uniform throughout the contaminated interval (between <0.11 ppm and

275   2.90 ppm from 0 to 55 cm) and are highly enriched at 70 to 75 cm (23.96 ppm), with minor

276   enrichment at 60-65 cm. A similar peak in trace element content of pyrite in the 70 to 75 cm

277   interval is present for Ni, Co and Mo (35.0, 83.8 and 22.1 ppm respectively) despite these

278   elements not being noticeably enriched in any section of the core. Gold behaves similarly,

279   however its interval of major enrichment occurs between 60 and 65 cm below the main zinc

280   enrichment. The Te content of pyrite is not enriched at any level in the core, however it is

281   significantly enriched compared to the Huon core despite both cores having similar bulk Te

282   contents. Both Au and Te are enriched in pyrite compared to the bulk sediment.

283   The LA-ICPMS data is collected every 0.1-0.5 s as the laser ablates through the framboid and

284   this data can help to distinguish which elements are held within the pyrites structure/micro-

285   inclusions within the pyrite or as larger inclusions within the framboid. Elements that exhibit

286   relatively flat traces throughout the laser ablation are thought to be contained within the

287   structure or micro-inclusions while elements with distinct peaks are thought to exist as larger

288   inclusions (Thomas et al., 2011). Based on these criteria As, Mn and Zn appear to be held

289   within the pyrite structure or as micro-inclusions; Te, Au and Sb are held as inclusions and

290   Cu, Pb and Ag are contained in the framboids as both inclusions and contained within the

291   pyrite structure or microinclusions (Figure 5).

Discussion

292

293   Previous enquiries into the accumulation of trace elements in pyrite forming within sediments

294   have shown that mechanisms that incorporate different trace metals into pyrite proceed at

295   different rates. These are, in decreasing order: As = Mo > Cu = Fe > Co > Ni >> Mn > Zn >

296   Cr = Pb > Cd (Morse and Luther, 1999). These were determined using modifications by

297   Huerta-Diaz and Morse (1990) on the pyrite extraction method proposed by Lord (1982) to

298   determine the percentage of different trace metals and metalloids incorporated into pyrite,

299   termed the degree of trace metal pyritization. As this method is not selective for pyrite, it is

300   only applicable in areas where no other sulfides or minerals with similar chemical properties

301   to sulfides occur. Our study differs in that the LA-ICPMS technique allows us to analyze

302   selected pyrite framboids individually which greatly expands the potential areas of study.

303   Incorporation of metals and metalloids occurs by a number of different ways (Rosso and

304   Vaughan, 2006). Which of these, or combination of these, mechanisms occur for the

305   different elements effects how much of them can be incorporated into the individual

306   framboids and the rate of incorporation. These interactions of metals and metalloids with the

307   surface of the growing pyrite are controlled by several factors: equilibration time, solution

308   pH, initial concentration of elements, particle size, temperature (Borah and Senapati, 2006)

309   and point of zero charge (Pikaray et al., 2005).

310   However, micro-environments with different pH or trace element concentrations may have

311   formed locally within the sediment. The existence of these micro-environments may explain

312   the spread that is evident for trace element content of pyrite in the same sediment interval

313   (Hochella et al., 2005; Xia et al., 2009).

314   Arsenic is enriched in pyrite by approximately an order of magnitude in both the high metal

315   content Derwent and low metal Huon Estuaries when compared to the whole rock sediment

316   analyses. The only interval where this does not hold is in the most contaminated section of

317   the Derwent core where several framboids have lower arsenic content than that measured in

318   the host sediment. This is due to much of the As being held in other phases (such as

319   arsenopyrite) in this interval that is not available for incorporation into pyrite (Figure 6). This

320   is because As readily substitutes into pyrite at a high rate; which makes incorporation into

321   pyrite the primary mechanism in which As is removed from pore water (Lowers et al., 2007).

322   This is supported by SEM analyses (Gregory et al., 2013) that show the presence of

323   arsenopyrite in the metal enriched sections of the sediment.

324   Molybdenum behaves differently than expected with several framboids displaying erratic

325   enrichment relative to the host sediment in the contaminated zone and an increase in the Mo

326   in pyrite below the contaminated zone at 70-75 cm. Molybdenum exists in the sediment as

327   the molybdate or thiomolybdate anion or one of the intermediates between these two end

328   members (Erickson and Helz, 2000; Helz et al., 1996; Xu et al., 2006). Of these, the

329   thiomolybdate anion is likely to be in highest abundance in the sulfide rich conditions of the

330   sediments (Erickson and Helz, 2000). This is also the most efficient form to adsorb onto

331   pyrite, however it is also the most efficient form to adsorb onto organic matter (Erickson and

332   Helz, 2000; Helz et al., 1996). In the Derwent samples there is significantly more organic

333   matter above 45 cm depth (Gregory et al., 2013), which is where the Mo content of pyrite is

334   comparatively low. This suggests that competition between pyrite and organic matter for

335   adsorption of Mo may be responsible for the observed lower Mo content of pyrite above 45

336   cm. In the uncontaminated Huon Estuary molybdenum holds with the predictions of Morse

337   and Luther (1999) with the medians of the Mo in pyrite above that in the host sediment. The

338   trends with depth also fit with the predictions by Huerta-Diaz and Morse (1992), which

339   predict an increasing trace metal abundance with depth; in the Huon we see this trend below

340   30 cm of sediment depth (Figure 4).

341   Water exchange rate kinetics for Pb and Zn are faster than that for iron which suggests that

342   Pb and Zn sulfides should precipitate earlier than pyrite (Morse and Luther, 1999). The

343   incorporation of these metals in pyrite is also favored under the conditions found in the saline

344   sediments as the pH found in the sediments is above the adsorption edge for these metals on

345   pyrite (Jean and Bancroft, 1986). Our data support this result in the Huon Estuary where the

346   time resolved LA-ICPMS output graphs show relatively spikey compositions of Pb and Zn

347   (Figure 5), suggesting the presence of inclusions of these elements as sulfide inclusions

348   within the pyrite. The time resolved LA-ICPMS data from the Huon samples also indicates a

349   decrease in the amount of Pb and Zn from the center of the framboid to the edge. This is

350   consistent with early rapid crystallization of Pb and Zn sulfides, which are associated with the

351   earliest growth of pyrite framboids. In the contaminated sediments of the Derwent Estuary

352   lead and zinc behave somewhat differently with relatively consistent compositions

353   throughout the pyrite framboid (Figure 5). This may be due to the amount of available zinc

354   and lead (from the first four steps of the sequential leach data), which increases from 1935

355   ppm and 1415 ppm respectively in the 20-25 cm interval to 4750 ppm and 4645 ppm

356   respectively in the 50-55 ppm interval (Table 1 and Figure 6). This results in the observed

357   increase in Pb and Zn in the framboids. These metals occur most likely as several micro-

358   inclusions that are evenly distributed throughout the framboid. Though the exact mineral that

359   forms the nanoparticles was not determined studies by Berner et al, (2013) and Deditius et al.,

360   (2011) has shown that Zn and Pb often exist as sulfide nanoparticles in pyrite; therefore it is

361   probable that the nanoparticles are sulfides. This inclusion hypothesis is supported by work

362   from Deditius et al. (2011) which has shown that a wide range of nano particles are found in

363   pyrite as native metals, sulfides, sulfo-salts and iron bearing nanoparticles. In the course of

364   their study they showed that Pb, Bi, Sb, Au, Ag, Ni, Te and As preferentially distribute into

365   nano particles, with large particles forming by exsolution and small ones forming by direct

366   precipitation. However, they did not investigate Zn, in this study Zn appears to behave

367   similarly to Pb and thus it is suggested that it too preferentially forms nano particles in pyrite.

368   Zinc tends to be accumulated in pyrite less than Pb and Cu, relative to the total amounts of

369   Zn, Pb and Cu in the system. This may be because the pK_1 for the formation of the $MeOH^{z-1}$

370   complexes are higher for Zn (8 for Cu, 7.7 for Pb and 9 for Zn) (Baes and Mesmer, 1976),

371   resulting in less efficient Zn adsorption (Müller et al., 2002). A wide degree of variation in

372   the content of Pb and Cu is found, especially within the most contaminated zones. This may

373   be due to competition for the same adsorption sites, similar to that noted by Müller et al.

374   (2002).

375   In our experiment Cu behaves very similarly to Pb and Zn, as predicted by water exchange

376   reaction kinetics (Morse and Luther, 1999). This is not surprising as Cu adsorption on pyrite

377   has been shown to be rapid and at pH over 5 (Wang et al., 1989). Similar to Pb and Zn, the

378   Cu in framboids from the uncontaminated Huon Estuary sediments has a spiky (inclusion-

379   rich) distribution with an overall decrease in Cu towards the rims of the framboid (Figure 5).

380   In the Derwent Estuary sediments Cu in the framboid is less spikey than in that the Huon

381   River framboids but more spikey than the Derwent Pb and Zn.

382   Gold content in pyrite was found to be subdued in the most metal enriched part of the

383   Derwent core, with the highest gold in pyrite present below the major metal enrichment. The

384   Au precipitates from pore waters either by adsorbing onto sulfides or other materials (Jean

385   and G Michael, 1985; Maddox et al., 1998; Mycroft et al., 1995; Renders and Seward, 1989;

386   Schoonen et al., 1992; Widler and Seward, 2002; Woods, 1996) or by precipitation due to

387   bacterial mediated precipitation of gold metal (Gwynne, 2013; Hough et al., 2011; Lengke et

388   al., 2006; Reith et al., 2009). Schoonen et al. (1992) showed that pyrite is a very good

389   scavenger of gold in natural systems. This is achieved by the adsorption of gold on the

390   surface of the growing crystals with incorporation into the structure of the pyrite by

391   subsequent over growth. However, gold is also adsorbed by organic matter through biologic

392   pathways (Zhang et al., 1997). The top of the sediment section in the Derwent core contains

393   a higher amount of organic matter (Gregory et al., 2013) and in this region pyrite framboids

394   tend to also have lower Au content. This suggests that more of the available Au is adsorbed

395   onto organic matter resulting in less gold accumulation in pyrite. Müller et al. (2002) showed

396   that high concentrations of Cu, Pb and Zn prevented the adsorption onto pyrite of Au in

397   pyrite rich mine tailings. It is possible that this process is occurring in the Derwent core,

398   where additional competition for surface adsorption sites from Pb, Zn and Cu in the

399   contaminated zone has resulted in relatively low Au incorporation into pyrite fraction (Figure

400   6 and Table 1). Another possibility is that bacterial meditated precipitation of Au is enhanced

401   at this depth. Several studies (Gwynne, 2013; Lengke et al., 2006; Reith et al., 2009) have

402   shown that sulfate-reducing bacteria can precipitate nanoparticle Au in conditions where

403   pyrite can be formed. We consider this mechanism to be plausible in our samples as our data

404   show the small inclusions of Au that are expected from this mechanism and the Au nano-

405   particle fixing bacteria (*Cupiavidus metallidures*) has been identified in Australian field sites

406   (Reith et al., 2006).

407   Another factor likely to effect the uptake of Au in pyrite framboids is the presence or lack of

408   As. Several studies have shown that coatings of As on the surface of iron sulphides greatly

409   enhance the adsorption of Au on pyrite and higher As concentrations are often associated

410   with higher Au concentrations (Deditius et al., 2008; Deditius et al., 2009; Deditius et al.,

411   2011; Hough et al., 2011; Mikhlin et al., 2011; Reich et al., 2005; Reich and Becker, 2006).

412   While the presence of As in pyrite has probably aided in the adsorption and accumulation of

413   Au in pyrite in the Derwent samples As is not significantly enriched in the sections where

414   strong Au enrichment is observed. Thus, relative As enrichment in pyrite probably did not

415   result in relative enrichment of Au in pyrite.

416   Inclusions were found to be an important host of the Ag in diagenetic pyrite. This is

417   consistent with several other studies that have found silver to form Ag metal or Ag sulfide

418   micro particles on or in pyrite (Deditius et al., 2011; Mikhlin et al., 2011; Müller et al., 2002;

419   Pooley and Shrestha, 1996). Previous studies have suggested that these form first as films of

420   Ag_2S that can consolidate into round nanoparticles. Over time these sulphides can

421   decompose to Ag metal (Mikhlin et al., 2011). Similarly to Au, the Ag in pyrite is at a

422   maximum below the major zone of metal contamination (Figure 4). The pK_1 for the $MeOH^{z-}$

423   ^{1} of Ag is 12 (Baes and Mesmer, 1976), which suggests that the pH conditions of the

424   sediments are not as ideal for Ag adsorption on pyrite as for some other elements (notably

425   Cu, Pb and Zn) (Müller et al., 2002). This coupled with a far greater amount of competition

426   for binding sites with Cu, Pb and Zn higher in the section resulted in relatively low Ag in

427   pyrite in the more metal enriched part of the sediment and high Ag in pyrite below the major

428   metal enrichment. This is similar to explanations given for low Ag adsorption in zones of

429   high Pb, Cu and Zn adsorption for studies of mine tailings (Müller et al., 2002).

430   The Ni content of pyrite is generally subdued in most of the Derwent pyrite, despite Ni

431   commonly being enriched in pyrite. This is due to the general low levels of Ni in the system.

432   The amount of Co in pyrite is similarly subdued, though not to the extent of Ni and probably

433   stems from a similar lack of Co available for adsorption (Figure 6). Competition for

434   adsorption sites on the pyrite may also play a role in the low levels of Ni and Co in the metal

435   enriched sections. This would explain why the highest average Ni and Co enrichment is

436   found in pyrite from the 70 to 75 cm section, coincident with the highest Ag in pyrite. This

437   again is consistent with the explanation for lower adsorption of less abundant trace metals on

438   pyrite when there is significant competition for adsorption sites by Müller et al. (2002).

439   The reason for the high Te measured within the Derwent pyrite framboids compared to the

440   Huon framboids is not immediately clear, particularly as the total amount of Te (whole

441   sediment) are similar. It may be due to complexing between tellurium and other elements

442   (such as gold) in solution, causing the tellurium to be adsorbed onto the pyrite with the other

443   metals or that Te in the Huon is hosted in an insoluble detrital mineral and is not available for

444   incorporation into pyrite.

445   As there is no data for the amount of mobile Au, Ag and Te available in the sediments at

446   different depths due to analytical difficulties with measuring these elements in the sequential

447   leaches, we cannot be certain of our competition for adsorption site hypothesis for siting of

448   these elements in diagenetic pyrite. Other explanations for the observations may be that the

449   Au, Ag and Te are entirely held within immobile phases such as franklinite or sulphides in

450   the more contaminated zones and held within more soluble phases, such as organic matter

451   immediately below the contaminated zone. We see this explanation as unlikely because the

452   source of the Au, Ag and Te appears to be the smelter waste and for it to diffuse down to

453   enter the pyrite below the contamination it would have to be mobile and thus would be

454   available for incorporation into the pyrite earlier as well. A second possibility is that trace

455   metal incorporation is at least to some degree controlled by biological processes and the

456   organisms that are needed cannot live in the high metal conditions of the higher sections of

457   the core. Though this is an interesting possibility it is well out of our field of expertise and

458   we are unable to test it at this time.

459   This is the first study that has analysed pyrite framboids that have formed in a contaminated

460   estuary. It shows the amount of trace elements that can be incorporated into pyrite and thus

461   be rendered unavailable for biological uptake. The study also shows how the incorporation

462   of some more concentrated trace elements can limit the incorporation of other trace elements.

463   The use of LA-ICPMS has allowed the analysis gold, silver and tellurium in sedimentary

464   pyrite, something not possible using traditional sequential extraction techniques. This

465   demonstrates some of the factors that affect the uptake of these elements in sedimentary

466   pyrite which is of particular interest now as recent models for ore deposits suggest pyrite is an

467   important source for some metals and metalloids.

673
674 **Figure Captions**

675 Figure 1: Location of samples taken from the Derwent (SM1001) and Huon (H1) Estuaries.

676 Hatched patterns indicate residential areas.

677 Figure 2: Scanning electron microscope images of pyrite framboids from the Derwent

678 Estuary (A and B) and the Huon Estuary (C to F). The framboids are very similar between

679 the relatively uncontaminated Huon Estuary and the contaminated Derwent Estuary.

680   Figure 3: Whole sediment geochemical analyses of sediment cores from the Derwent (red)

681   and Huon (blue) Estuaries. The Derwent estuary is enriched in metals and metalloids in the

682   top 45 cm, very enriched from 45-55 cm and tapers down to background values by 75 cm.

683   Figure 4: Whole sediment analyses (red squares) and LA-ICPMS analyses (blue circles) of

684   pyrite framboids from the Derwent (left) and Huon (right) Estuaries.

685   Figure 5: Time resolved LA-ICPMS output graphs of pyrite framboid analyses for Derwent

686   and Huon Estuaries. The trace of the iron (when above 1000000 counts) shows where pyrite

687   is being ablated. Spikes in the plots show microinclusions within the pyrite while relatively

688   flat plots indicated the elements are held within the pyrite structure. The framboids are

689   mounted in epoxy then polished down resulting in the laser starting in the center and ablating

690   to the edge.

691   Figure 6: Trace metal contents of pyrite, whole sediment and trace metals available to be

692   incorporated into pyrite. Note that both Pb and Zn have very high proportions of metals that

693   can be incorporated into pyrite. This may cause some metals to be unable to adsorb onto the

694   surface of the growing pyrite allowing them to diffuse to lower levels in the sediment and

695   become incorporated into the pyrite there.

696   **Tables**

697   Table 1: Trace metals that are easily exchanged, weakly complexed and bound by carbonates,

698   bound by Mn (hydr)oxides and bound by organic matter from the Derwent Estuary sediments

699   as determined by Gregory et al. (2013).

Depth Interval (cm)	Lead (ppm)	Manganese (ppm)	Cobalt (ppm)	Nickel (ppm)	Copper (ppm)	Zinc (ppm)	Arsenic (ppm)	Cadmium (ppm)	Molybdenum (ppm)
