6   Abstract

7   Natural olivine dissolution and replacement often occurs preferentially along specific

8   crystallographic planes. Thus, olivine reactivity at specific surfaces was examined in situ using

9   phase-shift interferometry, which has a detection limit $<10^{-5}$ nm/sec, by dissolving two smoothed

10   olivine crystal faces and a third sample corresponding to a surface that was generated by

11   preferential dissolution along structural defects. The experiments were conducted at 22 °C and

12   ambient pressure in 0.1 M NaCl solutions that were acidified to pHs between 1 and 4 using 0.1 M

13   HCl. These experiments show that olivine dissolution can vary from one surface to another as

14   well as in different areas of the same surface that have similar characteristics. The fastest vertical

15   retreat occurred at the surfaces related to defects. However, only vertical advancement was

16   observed at pH 1 on this surface consistent with the observation of isolated islands on the surface

17   during atomic force microscopy investigations after the experiment. Raman analysis of the

18   precipitated phase showed that it was not one of the thermodynamically stable phases expected

19   from PHREEQC modeling. However, the correlation between the siloxane ring peak of

20   amorphous silica with a similar peak in the precipitate spectrum, in conjunction with previous

21   experimental and natural observations, indicates that the precipitate was a Si-enriched amorphous

22   phase. Therefore, precipitation can facilitate the further dissolution of olivine on this surface as

23   long as it does not completely armor the surface. Precipitate formation on surfaces associated

Revision 1

24 with outcropping defects supports the natural observations of preferential dissolution and

25 serpentinization along these defects implying that the fast dissolution of these surfaces will play a

26 critical role during olivine replacement. In addition, comparison with flow-through experiments

27 indicates that outflow fluid chemistry may provide an incomplete picture of processes occurring

28 during olivine dissolution.

29 Keywords: Interferometry, dissolution, precipitation, olivine

30

31   1. Introduction

32 Olivine has recently been recognized as a key mineral for many environmental remediation

33 schemes such as acid mine drainage (Kleiv and Thornhill, 2008), CO_2 (Jarvis et al., 2009) and

34 sulfur sequestration (Rappold and Lackner, 2010). In addition, the natural reaction of olivine with

35 fluids plays an important role in acidic fluid neutralization (Varekamp et al., 2009) and its

36 reaction with seawater to produce serpentine minerals has important consequences for the

37 rheology and geochemistry of the oceanic lithosphere (Escartin et al., 1997, Bach and Früh-

38 Green, 2010). Although extensive research has been conducted into olivine reactivity most

39 olivine dissolution experiments are limited to flow-through experiments that use ground olivine

40 (e.g., Oelkers, 2001; Pokrovsky and Schott, 2000). However, there is evidence that in nature

41 olivine dissolution occurs preferentially along specific crystallographic planes. For example,

42 olivine that has undergone mantle flow has an anisotropy that causes parting along specific

43 directions enabling the (010) surface to become accessible to fluids (Boudier et al., 2010). In

44 experiments, dissolution of ground olivine also produces surface features that are attributed to

45 preferential dissolution at dislocations and different cleavage planes (Grandstaff, 1978). Awad et

46 al. (2000) studied dissolution at the (010), (100) and (001) surfaces of olivine and showed that

2

Revision 1

47   preferential dissolution occurred at the (010) surface. However, the experiments of Awad et al.

48   (2000) were conducted by cutting and mechanically polishing an orientated olivine crystal and

49   measuring the crystal size periodically to determine the dissolution rate. Previous work on calcite

50   dissolution indicates that this method of sample preparation can increase the dissolution rate due

51   to the formation of defects associated with mechanical grinding (Macinnis and Brantley, 1992).

52   To explore the dependence of crystallographic orientation on olivine dissolution we have

53   performed in-situ measurements using phase-shift interferometry (PSI) experiments on three

54   distinct olivine surfaces. The results of this study advances our understanding of preferential

55   olivine dissolution as well as the concomitant precipitation of new phases that also occurred

56   during our experiments and have been observed in nature (Boudier et al., 2010) and previous

57   experimental investigations (Davis et al., 2009; King et al., 2010).

58

59   2.   Methods

60   Naturally well-defined faces of gem quality euhedral forsteritic olivine crystals from the Sapat

61   Complex, Kohistan, Pakistan were used as the starting material (Fig. 1). Samples of the surfaces

62   were sliced along the crystal faces by sticking the surface face-down onto a glass slide and

63   cutting it into 3 x 3 x 1 mm microchips. The glass slide and glue were then removed using

64   acetone. Although the faces are macroscopically well defined, the surfaces had a roughness that

65   was too high for direct use in PSI experiments. Thus, we chemically smoothed the surfaces prior

66   to the experiment using the 'spinning method' in which the crystal is spun in 0.12 M HF solution

67   at 20 °C until portions of the surface were flat enough to produce clear interference fringes on the

68   PSI. Using HF acid spinning also cleaned the surface of any trace of the fibrous serpentine

69   minerals that are associated phases with olivine crystals from the Sapat region (Bouilhol et al.,

3

Revision 1

70   2012). This treatment should prevent the formation of a Si-enriched layer on the olivine surface,

71   as proposed by Pokrovsky and Schott (2000), because the Si can also be removed as soluble

72   silicon fluorides. The spinning time needed to achieve the required degree of smoothness was

73   dependent on the initial surface roughness but was typically a few minutes. The HF solution was

74   renewed every second minute to prevent the saturation of silica. After smoothing, the surfaces

75   were ultrasonically cleaned in deionized water. Due to the formation of large etch pits after

76   smoothing, the crystallographic orientation of the individual surfaces could not be easily

77   measured. Therefore, the original crystallographic orientation of the crystal face, shown for a

78   typical crystal in Figure 1, was taken as the surface present.

79   A 0.1 M NaCl solution was prepared from solid reagents dissolved in deionized water. This

80   solution was then placed in a sealed container and heated in an oven at 40 ºC overnight to reduce

81   the concentration of dissolved gases. To obtain solutions with a range of pHs 0.1 M HCl was

82   carefully added to this solution.

83   Phase-shift interferometry provides nanoscale resolved measurements of ultra-slow growth and

84   dissolution of minerals (e.g., van Driessche et al., 2011) with a detection limit of $<10^{-5}$ nm/sec,

85   depending on the stability of the machine, light wavelength and refractive index of the solution or

86   mineral (e.g., Ueta et al., 2013). This technique has the benefit of a larger lateral area of study

87   than that of other in-situ experimental methods such as atomic force microscopy (AFM) and can

88   be used to obtain long-term measurements of dissolution and growth (see e.g. Green and Lüttge,

89   2006). The olivine dissolution measurements were conducted on the Fabulous phase-shift

90   interferometer built in-house at Tohoku University, which uses modified Linnik-type interference

91   optics and a white light source. A detailed description of the technique can be found in the

92   appendix and Satoh et al. (2007). To set up the experiments samples were first attached to the

4

Revision 1

93   sample mount using silicone glue and gold particles deposited on the surface. The sample mount

94   was then secured into the sample cell, which was subsequently closed. The sample cell was

95   flushed with deionized water to wash the surface before the experiment and to remove any

96   unstable gold particles. During flushing, bubbles were removed by gently tapping the sample cell.

97   The sample cell was held at 22 °C ±0.2 °C (the temperature of the clean-room). The fluid was

98   pumped through the cell using a syringe pump with a flow rate of 40 µL/min resulting in a linear

99   velocity of 15 µm/sec at the dissolving surface. Each surface was reacted with the 0.1 M NaCl

100   solution (pH 5.9) followed by pH 4, 3, 2 and 1 solutions. The reactant solutions were run through

101   the reaction cell for at least 10 minutes prior to the beginning of the experiment to purge the cell

102   of the previous solution. When all experiments on a surface had been completed the sample cell

103   was flushed with ethanol and immediately opened to prevent further reaction of the olivine with

104   the solution. After each experiment the whole fluid cell was cleaned in an ultrasonic bath using a

105   dilute HCl solution followed by deionized water and air dried.

106   Changes in surface roughness were used to provide additional information about the dissolution

107   and growth occurring at the different olivine surfaces. Surface roughness was examined for areas

108   of the surface (30 x 33 pixels, 9.0 x 9.9 µm) surrounding each of the points analyzed for vertical

109   velocity. Two parameters, *Ra* and *Rz*, were calculated for the roughness following the procedure

110   of Fischer and Lüttge (2007). *Ra* is a measure of the overall surface roughness and was calculated

111   by separating each of the areas into lines, taking the standard deviation of the grayscale intensity

112   for each line separately and then calculating the arithmetic mean of the standard deviation of all

113   the lines within the individual areas on the surface. The change in *Ra* during the experiment was

114   then calculated as $\Delta Ra = Ra_{end} - Ra_{beg}$.

115   The second roughness parameter *Rz* determines the deviation of the five highest (z_{pi}) and five

116   lowest (z_{vi}) grayscale values from the mean grayscale for a designated area and can provide

5

Revision 1

117   information about how individual mineral surface areas are dissolving and thus changing in

118   roughness. For example, a negative value of Rz indicates that the surface area had a few points

119   with a very low height or grayscale value however the mean grayscale value was similar to the

120   majority of points used in the calculation i.e., there were specific, isolated lower points in the area

121   examined. A positive value of Rz suggests that the surface was comprised of high islands whilst

122   the average grayscale for the surface and thus majority of the surface area was comparatively

123   low. The Rz parameter was calculated using

124
$$R_z = \frac{\sum_{i=1}^{5}(z_{pi}-\mu)+\sum_{i=1}^{5}(z_{vi}-\mu)}{5}$$

125   where the average (μ) was calculated using

126
$$\mu = \frac{1}{MN}\sum_{k=0}^{M-1}\sum_{l=0}^{N-1} z(x_k y_l) \ .$$

127   The difference in Rz roughness between the beginning and the end of the experiment (ΔRz) for

128   each area was taken using the same procedure used to determine ΔRa.

129   The (021) surface was also examined using a Digital Instruments Nanoscope III Multimode

130   atomic force microscope (AFM) (Digital Instruments, Bruker) because AFM has a better x-y

131   resolution than PSI. The AFM was equipped with a Si_3N_4 tip (Veeco Instruments tip model NP-

132   S20) with spring constants 0.12 N/m and 0.58 N/m. Images were taken in contact mode and

133   analyzed using the Nanoscope software (Version 5.31r1).

134   Raman spectroscopy was used to try to identify the precipitated phase. Raman spectra were

135   collected with a high-resolution Jobin Yvon HR800 Raman spectrometer using the 532 nm line

136   of a 14 mW Nd-YAG laser calibrated using the 520.7 cm^{-1} band of silicon. After passing through

137   a 100 µm entrance slit the scattered Raman light was dispersed by a grating of 1800 grooves/mm.

138   A hole size of 100 µm was used to limit the penetration depth of the laser into the sample. The

6

Revision 1

139   Raman spectra from the sample were compared to RRUFF project (Downs, 2006) reference

140   spectra of the most thermodynamically stable phases calculated using the geochemical modeling

141   program PHREEQC (Parkhurst and Appelo, 2000). The simulations were conducted with

142   different surface areas beginning with a 3 mm x 3 mm flat surface. The effect of different fluid-

143   solid ratios was also examined because the exact amount of solution between the glass window of

144   the PSI sample cell and the crystal was unknown. The Lawrence Livermore National Laboratory

145   database was used in the simulations.

146

147   3. Results

148   Dissolution was observed on all surfaces during the experiments and was accompanied by the

149   formation of etch pits comparable in shape to those observed during natural weathering by Velbel

150   (2009). The average vertical retreat velocities for each surface can be found in Table 1 and a plot

151   of the different rates of surface retreat in Figure 2. Step retreat velocity shows a strong correlation

152   with the solution acidity where the rate of step retreat increased with decreasing solution pH (Fig.

153   2c).

154

155   3.1   Crystal faces

156   The (010) surface had large flat areas with striations before the HF treatment. According to Jan

157   and Khan (1996) the striations are parallel to the c-axis [001] direction. During a smoothing test

158   extensive dissolution of the (010) surface produced square etch pits that were aligned with the

159   striations already present on the surface. The shape of the etch pits and their alignment to form

160   channels was consistent with those observed by Kirby and Wegner (1978) on a cut and polished

161   (010) surface.

7

Revision 1

162   During the dissolution experiments minimal change in the surface features was observed.

163   Dissolution at the (010) surface showed a gradual increase in the rate of normal surface retreat as

164   the pH was lowered. Indications of rising surface height were observed in the pH 1 experiment,

165   however, it was followed by a period of dissolution and thus was attributed to an instability of the

166   gold surface during the first part of the experiment. Only olivine peaks were observed in the

167   Raman spectrum, thus no new phases were detected within the uncertainties of the measurements.

168   The area studied on the (110) surface consisted of smooth areas of surface that had smaller

169   rougher areas between them. Similarly to the (010) surface, the (110) surface morphology did not

170   change dramatically during the experiment. Reaction of the (110) surface was conducted at pH 1

171   and pH 6 only for comparison to the rates from the (010) surface. Increase in the surface height

172   was found for all points on this surface at pH 6, however only retreat of the surface was observed

173   in the pH 1 solution. The retreat determined for the pH 1 solution was faster than observed for the

174   (010) surface with the same solution. As for the (010) surface, no precipitation was observed on

175   the (110) surface after the experiments.

176

177   3.2 Defect-related surface

178   The (021) surface was examined prior to the experiments using AFM due to the presence of

179   some unexpected surface features. The AFM images of the starting surface show that the studied

180   area of this surface is composed of terraces (Fig. 3a) with the step faces consisting of etch

181   hillocks (also known as mammillary structures) similar to those observed in natural weathering

182   (Velbel, 1993) and during olivine dissolution in experiments (Grandstaff, 1978; King et al. 2010).

183   The steps have an average height of 90 nm and the etch hillocks along the step face have a

184   maximum width of 120 nm. Some of the smaller steps were only 45 nm in height. During

Revision 1

185   dissolution and growth the stepped structures became less prominent (Fig. 3b), except at the etch

186   pit walls.

187   Vertical retreat rate of the (021) surface increased with increasing acidity until experiments at pH

188   1 and 2 where all points showed an increase in the height of the surface. Specific spots on the

189   surface also showed an increase in height at lower acidities, pH 4 and 6, however only surface

190   retreat was observed in the experiment at pH 3. To determine whether the formation of a new

191   phase was the cause of the height increase, the surface was also examined using AFM after the

192   experiments (Fig. 3b). The AFM image confirmed the presence of a new phase on the surface

193   that consisted of rounded islands with one slightly elongated axis. Small islands covered the

194   entire surface and had a maximum width of 0.3 μm. The average height of the new phase was 14

195   nm, however the AFM image shows evidence that further nucleation and growth occurred on top

196   of existing islands forming stacks up to 50 nm high. In some areas large particles of up to 1 μm

197   height were also observed.

198   We attempted to characterize the newly formed islands using Raman spectroscopy on the (021)

199   sample (Fig. 4). Small, broad bands at 489 and 709 cm^{-1} that were not found in the reference

200   olivine spectrum can be attributed to the precipitated phase. To help identify the precipitated

201   phase the reaction was simulated using the geochemical modeling program PHREEQC assuming

202   a system with no flow. This enabled us to predict the most thermodynamically stable phases

203   expected under experimental conditions where growth was observed. In the 0.1 M NaCl solution

204   (pH 6) the simulations showed that when a surface area of 0.3 cm^2 or greater was present the

205   system was supersaturated with respect to hematite and talc. In contrast, at pH 1 the fluid is

206   predicted to be supersaturated with respect to amorphous silica and talc (and obviously also with

207   respect to other more stable crystalline silica phases that are unlikely to crystallize at 22 °C).

208   Therefore, talc and amorphous silica were taken as reference phases to compare with the Raman

9

Revision 1

209   spectrum of the phase precipitated in the pH 1 experiments along with the phase sepiolite, which

210   has been observed to form in low temperature experiments where talc or serpentine are expected

211   to be thermodynamically stable (Wollast et al., 1968). Of the peaks associated with the precipitate

212   only the peak at 489 cm^{-1} had a similar peak in the reference spectra for the most stable phases

213   predicted by thermodynamic calculations. This peak is comparable to the broad peak in the

214   amorphous silica spectrum that is assigned to 4-membered siloxane ring structures (Sharma et al.,

215   1981).

216

217   3.3 Roughness analysis

218   The results of the roughness analysis are shown in Figure 5. During the reaction of the surface

219   with low acidity solutions the different areas of the surface exhibit minimal scatter of ΔRa (Fig.

220   5a). This scatter in ΔRa increased for the individual areas for experiments with solutions of

221   increasing acidity. Each surface showed an equal number of areas that had increased and

222   decreased in Ra, with the exception of the pH 3 experiment conducted with the defective (021)

223   surface, which displayed a large increase of Ra for the majority of the surface areas examined.

224   The change in Rz is more complicated to interpret than variations in Ra because the calculated Rz

225   values can have either a positive or negative value depending on the grayscale distribution. As

226   observed for the Ra parameter, the different areas on the surface exhibited different behavior with

227   respect to the Rz value. In all experiments, with the exception of the defective (021) surface

228   reacted with a pH 6 solution, there were areas that exhibited both an increase and decrease in Rz.

229   Some areas also changed from positive to negative values of Rz. For ΔRz the scatter of points for

230   each area showed a similar change to that measured using Ra (Fig. 5b). A few outlying points are

231   the exception to this observation, and showed a large decrease in ΔRz during the pH 1 experiment

232   on the (010) crystal face and a large increase in ΔRz for one area in the pH 3 experiment for the

10

Revision 1

233   defective (021) surface. These points also correlate to some of the lowest and highest ΔRa values

234   observed in the experiments (Fig. 5c). As can be seen from Fig. 5c, there was no systematic

235   relationship between an increase or decrease in ΔRa value in comparison to the ΔRz value for

236   each area.

237

238   4.   Discussion

239   4.1   Dissolution rates

240   Comparison of the surfaces showed that the surface reactivities follow the order defective (021) >

241   crystal face (110) > crystal face (010) thus each surface exhibited a different reactivity. As

242   temperature, pressure and flow rate were kept constant it can be inferred that this difference was

243   dependent on the original surface structure. Typically, the different reactivities of surfaces are

244   described using concepts such as the periodic bond chain (PBC) theory of Hartman and Perdok

245   (1955a, 1955b, 1955c). In this model the different surfaces on a crystal can be separated into

246   three different classes, F faces (flat faces), S faces (stepped faces) and K faces (kinked faces).

247   The faces are determined by the number of periodic chains of strong bonds (PBCs) within the

248   olivine structure along a specific direction that are associated with different surfaces. A K face

249   has no PCBs associated with it whereas an S face has only one PCB and an F face contains PCBs

250   in at least two different directions. These different classes of surface exhibit different reactivities

251   often with increasing reactivity in the order K > S > F. For olivine the majority of the crystal

252   faces observed on natural crystals are denoted as F faces, including the three faces that we have

253   studied ('t Hart, 1978). Therefore, the different surfaces should have similar stabilities. Recent

254   computational work by de Leeuw et al. (2000) shows that the stabilities and thus the reactivity of

255   the studied surfaces do not vary greatly when the surfaces are hydrated. Therefore, the high

256   reactivity observed for the (021) surface, particularly with solutions of pH 3 or lower, cannot be

11

Revision 1

257 adequately explained by the crystal face reactivity alone indicating that the high reactivity was

258 related to the terraces present on this surface.

259 Etch hillocks are attributed to preferential dissolution along specific crystal planes and

260 dislocations (Grandstaff, 1978). Thus the formation of etch hillocks at the step edges (Fig. 3a) on

261 the (021) surface indicates that the terraces present were uncovered due to preferential dissolution

262 along defects rather than normal surface retreat. Godinho et al. (2012) demonstrated that CaF_2

263 surfaces with a high step density have increased dissolution rates in comparison to flat surfaces

264 and therefore the vertical velocity measurements were normalized to the step density (see

265 Appendix). Comparison of the step retreat velocity (Fig. 2c) shows that at pH 4 and 6 the defect-

266 related terrace areas have a similar retreat rate to that observed on the (010) surface. However, at

267 pH 3 the rate of step retreat increased and was higher than that of the (010) surface, consistent

268 with the formation of precipitates on this surface at pH 2 and 1 due to the fast dissolution of the

269 defect related features. The relationship between the step density and the retreat rate as step

270 retreat velocity, also shows that the observed reactivity difference from the vertical retreat rates

271 can be attributed to the step, kink and dislocation density at the different surfaces.

272 Dissolution at acidic pHs for the (110) and (010) crystal face surfaces shows much more limited

273 dissolution than observed on the (021) surface. The increased reactivity of the (110) surface was

274 expected from PCB theory, which indicates that the (010) surface is more stable than the (110)

275 surface ('t Hart, 1978). However, the dissolution rates of the (010) and (110) surfaces remained

276 similar, as expected from considerations of the hydroxylated surface stabilities of 0.26 and 0.27

277 J/m^2 for the (110) and (010) surface respectively calculated by de Leeuw et al. (2000).

278 In pH 4 and 6 solutions the normal surface retreat determined in situ was faster than those

279 calculated for ground olivine in flow-through experiments (Pokrovsky and Schott, 2000) (Table

280 2, Fig. 6). The evidence for growth at pH 6 on the (110) and (021) surfaces and the expected

12

Revision 1

281   removal of only a few nms of material based on the measured dissolution rates, results in silica

282   layers similar in size to those previously observed on olivine (Hellmann et al. 2012), and

283   indicates that a relative rate could have been measured during the course of the experiments. If

284   this is the case, the real dissolution rates could be even faster. In contrast, dissolution at the (110)

285   and (010) crystal face surfaces examined in this study showed a similar dissolution rate at more

286   acidic pHs to those reported for flow-through experiments. This suggests that at higher pH, where

287   the dissolution of olivine is slower, anisotropy between the different surfaces plays a role in the

288   overall dissolution, whereas in low pH solutions where olivine dissolution is faster the effect of

289   anisotropic dissolution is not as important.

290

291   4.2 Surface reactivity

292   Recent in depth analysis of surface reactivity by Fischer et al. (2012) has demonstrated the

293   importance of reactivity distribution across a surface. The PSI pixel data samples a small area of

294   the surface (0.09 μm^2) and was limited to the terrace areas as the etch pits did not produce

295   reliable results, however, examination of the change in terrace area roughness can still provide

296   interesting insights into the changes of the surface during the experiments. The roughness

297   parameters calculated for the sample points also showed that on all of the surfaces each area

298   examined exhibited a unique behavior, however the overall behavior of the different surfaces is

299   similar under similar conditions, even between the defective (021) surface and the crystal faces.

300   For example, there is a similar scatter in dissolution rate in pH 6 experiments for both the

301   defective (021) surface and the planar (010) surface but *Ra* and *Rz* changed only minimally (Fig.

302   5). At pH 1 there is a similar variation in the retreat rates on both the (110) and (010) crystal faces

303   to that observed at pH 6 but there is a larger difference in the change in surface roughness at the

304   individual surface points. In addition, the change in roughness does not directly reflect the

13

Revision 1

305   reactivity of the surface measured by retreat rate as demonstrated by the relationship between rate

306   and Ra during the pH 3 experiments on the (021) surface (insert in Fig. 5a). The change in

307   roughness for each area also shows no correlation with the surface slope (Fig. 7) and therefore

308   suggests that the change in roughness of individual areas was not controlled by the higher

309   roughness associated with higher step density.

310   Similarly to the *Ra* roughness parameter, *Rz* also gives an indication of the homogeneity of the

311   olivine surface dissolution, however this parameter can also provide an insight into how the

312   individual areas on the surface dissolve. The largest changes in the *Rz* value are observed for the

313   pH where the fastest dissolution rate was observed. This correlates with the large increase in

314   roughness that was observed for the fastest dissolution rates with the Δ*Ra* parameter. However,

315   although the *Rz* parameter shows that as the solution acidity increased the different surface areas

316   exhibited different behavior no systematic decrease or increase in *Rz* was observed in relation to

317   the initial surface area morphology. The observation that individual areas can react differently

318   and non-systematically during each experiment highlights the importance of examining many

319   different spots during the in-situ analysis of olivine dissolution. In particular, it highlights the

320   importance of examining the 'rate spectra' for a surface, as described by Fischer et al. (2012), to

321   establish a thorough understanding of how a surface dissolves. However, the importance of these

322   rate spectra also needs to be examined at different conditions, as the olivine PSI experiments

323   indicate that although changes in roughness may vary dramatically across surface areas with very

324   similar characteristics, i.e., a terrace rather than a step area, the impact on the actual reactivity,

325   reflected in the dissolution rate, does not necessarily mirror this change in roughness.

326

327   4.3 Precipitation

14

328   Increasing surface height during the PSI experiments is related to the growth of new phases at the

329   surface. From the experimental results two different growth events can be determined. The first

330   growth was observed during reactions with the pH 4 and 6 solutions and the second with the pH 1

331   and 2 solutions. The first growth event at low acidity is expected to be limited, as only a few

332   points on the (021) surfaces exhibited growth. The further dissolution of the surface at all points

333   examined on the (021) surface and the similarities of the dissolution rates for each point on the

334   surface indicates that the new phase was metastable and redissolved or stopped growing, thus at

335   pH 3, only dissolution of the olivine was detected. For the (110) surface the purging of low

336   acidity solution before measuring the reaction with a high acidity solution was also expected to

337   have cleared the surface of any precipitated phases. The second growth event, observed on the

338   (021) surface terraces at high acidity, was more stable and resulted in the formation of islands of

339   a new phase on the surface. Growth was the dominant process on the defect-related (021) surface

340   at low pH because dissolution was not detected at any point analyzed on the surface during the

341   experiments at pH 1 and 2.

342   Olivine dissolution has been proposed to occur via the exchange of Mg for H^+ (protonation) from

343   the solution at the surface creating isolated silica tetrahedra that condense to form an amorphous

344   silica-rich layer (Pokrovsky and Schott, 2000). Computer simulations by Liu et al. (2006)

345   supported this hypothesis and showed that removal of the Si into solution is the rate determining

346   step of olivine dissolution. However, Zakaznova-Herzog et al. (2008) found no evidence for the

347   development of a Si-enriched leached layer. In our experiments the formation of islands of a new

348   phase and the increased height of the surface during the experiment indicates that precipitation

349   occurred rather than condensation of the silica tetrahedra that remain attached to the olivine

350   surface, which should show negligible height difference. The formation of similar precipitates

351   has been documented in many different silicate systems including wollastonite (Daval et al.,

15

Revision 1

352   2009; Ruiz-Agudo et al., 2012), diopside (Daval et al., 2013) and olivine at high acid

353   concentrations (King et al., 2011). These studies show consistent evidence for an interface-

354   coupled dissolution precipitation mechanism (Putnis and Putnis, 2007) for mineral replacement

355   where the dissolving mineral phase progressively increases the interfacial fluid saturation until a

356   critical supersaturation is reached and a new phase is precipitated. Further dissolution is

357   facilitated in this mechanism by the depletion of ions in the interfacial solution due to the growth

358   of the new phase. The continued vertical advancement of the surface and nucleation of new

359   islands suggests that the olivine surface continues to dissolve as the precipitate grows but that due

360   to the large distribution of the precipitates across the surface this could not be sampled

361   independently by the 0.3 μm pixel size.

362   PHREEQC calculations showed that the most stable phases expected to form in the reaction of

363   olivine with saline fluids at pH 1 and 2 are talc and amorphous silica, of which amorphous silica

364   had the highest supersaturation. Comparison of the Raman peaks assigned to the precipitated

365   phase with reference spectra for the theoretically stable phases revealed that the broad peak in the

366   amorphous silica spectrum that represents siloxane ring structures corresponded to the

367   precipitated phase peak at 489 cm^{-1}. Specifically, the sharper peak in the sample spectrum implies

368   that most of the siloxane ring structures are small 4-membered rings. However, the precipitated

369   phase also had a peak at 709 cm^{-1} that is not present in the amorphous silica spectrum, but is in an

370   area of the spectrum where intense peaks attributed to intra-tetrahedral linkages e.g., Si-O

371   stretching modes of bridging O atoms, within the silicate structure are found (Blaha and Rosasco,

372   1978; Huang et al., 2000; Kloprogge et al., 1999; McMillan, 1984). Hydrated amorphous Mg-

373   silicate phases are observed in nature (Rumori et al., 2004) and experiments (King et al., 2010) as

374   precursors to crystalline phases during olivine replacement. Therefore, in conjunction with

375   nuclear magnetic resonance studies, which have shown that the amorphous phase has a

16

376   composition similar to that of serpentine ($Mg_2Si_3O_5(OH)_4$) (Davis et al., 2009), we expect that the

377   precipitated phase is a hydrated amorphous Mg-silicate phase probably with additional Fe due to

378   the presence of Fe in Sapat olivine, as observed at higher temperature by Saldi et al. (2013) and

379   King et al. (2010). The precipitation of an amorphous phase indicates that the interfacial fluid

380   must have been highly supersaturated because amorphous phases are more soluble than their

381   crystalline counterparts.

382

383   5. Implications

384   The different reactivities observed on the olivine surfaces have important implications for

385   dissolution in the natural environment. Step retreat velocities imply that the terraces related to

386   defects present at the (021) surface dissolved at a similar rate to the (010) and (110) surfaces,

387   however, the outcropping of these defects at the (021) surface increased its reactivity. The fast

388   dissolution at the surface with etch hillocks also caused the precipitation of a Mg-silica phase in

389   solutions with a pH of 2 or 1. The overall effect of these precipitates on olivine dissolution is

390   difficult to quantify because further dissolution will depend on whether the precipitate completely

391   armors the surface. Precipitating phases that remove olivine constituent ions from solution can

392   aid olivine dissolution by increasing the undersaturation of the interfacial solution with respect to

393   olivine. However, the further dissolution of olivine will also be dependent on diffusion through

394   the precipitated layer as the reaction is controlled by the interfacial solution chemistry.

395   Densification of amorphous silica precipitates and therefore reduction in porosity is expected to

396   occur with time as the silica units condense or polymerize (Cailleteau et al., 2008), which would

397   slow dissolution and passivate the reaction, especially if Fe(III) is present (Saldi et al., 2013). In

398   contrast, the formation of columnar serpentine from the amorphous phase can provide fluid

399   pathways for the infiltrating fluid (Boudier et al., 2010) and is expected to create fracturing due to

17

Revision 1

400 volume expansion (Plümper et al., 2012a; Rudge et al., 2010). In olivine percolation experiments

401 solution flow rate has been shown to play an important role in the location of precipitation during

402 fluid infiltration (Andreani et al., 2009) with different phases precipitating in different flow

403 zones. Thus, future investigations should focus on the nucleation rate and the effect of different

404 temperatures and pressures on the phase precipitated to help clarify the effect of precipitation

405 during olivine dissolution.

406 The similarity between the dissolution rates determined at pH 3 and lower by Pokrovsky and

407 Schott (2000) using outlet fluid chemistry and this in-situ study indicates that the outlet fluid

408 chemistry of ground olivine experiments is controlled by the dissolution of surfaces similar to the

409 (110) and (010). This further implies that the effect of the faster dissolving surfaces associated

410 with outcropping defects cannot be observed from outlet solution concentrations due to the

411 concomitant formation of the amorphous Mg-silicate precipitates. These precipitates are limited

412 to specific surfaces at low pH and are below the imaging capability of methods such as scanning

413 electron microscopy that are typically used to examine surfaces after experiments. Thus,

414 experiments based on outflow fluid chemistry alone may provide an incomplete picture of

415 processes occurring during olivine dissolution. The in situ study also shows that olivine reactivity

416 with respect to dissolution can vary from one crystallographic surface to another as well as in

417 different parts of the same surface with similar characteristics, such as terraces. Finally, the

418 observation of precipitate formation on surfaces associated with outcropping defects supports the

419 natural observations of preferential serpentinization along these defects (Plümper et al. 2012b)

420 implying that it will be the reactivity of these surfaces that will control olivine reactivity in

421 nature. A recent discussion of the general implications of variable dissolution rates of different

422 crystal surfaces and their evolution with time, to conventional flow-through dissolution

423 experiments on powders can be found in Lüttge et al. (2013).

595   (red) and possible precipitated phases. All reference spectra are from the RRUFF project (Downs,

596   2006) with the exception of amorphous silica, which is from Majano et al. (2005). Peaks in the

597   sample spectrum assigned to the precipitated phase are highlighted by boxes. The spectra show

598   only the first 800 cm^{-1} of the spectra due to the swamping of the sample and olivine spectra by

599   the intense bands above 800 cm^{-1}.

600   Figure 5. (a) Plot of ΔRa values against the dissolution rates determined for each of the points.

601   Insert shows the rates of the pH 3 experiment against ΔRa on a linear scale. (b) Dissolution rates

602   plotted in relation to ΔRz, (c) Comparison of the change in Ra and Rz during the experiment.

603   Figure 6. Comparison between dissolution rates of olivine surfaces with those of Pokrovsky and

604   Schott (2000) for ground olivine powder.

605   Figure 7. Plots showing the relationship between the slope, thus step density, in each area on the

606   surface and the corresponding area's ΔRa roughness parameter (a) or ΔRz roughness parameter

607   (b).

617   **Appendix**

618   Phase-Shift Interferometry measurements and data reduction

619   Figure A1. Phase-shift interferometry. (a) Phase-shift interferometer set up and sample cell, top

620   and side view. (b) Example phase image from the (010) surface. Insert shows the height profile

621   along the yellow line as calculated from the interference fringes. (c) Time-space diagram of the

622   yellow horizontal line in (b). (d) Change in height plotted against time for surface points, where

623   the point for E is represented by the vertical yellow line in (d).

624   Interferometry is a well established technique that is based on the principle of superposition,

625   where two waves with the same frequency combine to form constructive or destructive

626   interference. In situ interferometry, such as phase-shift interferometry used in this study, uses

627   laser or filtered light at a specific wavelength that is split into two, one beam of which is reflected

628   off a reference mirror whilst the other is reflected from a single focal plane at a mineral surface

629   (Fig. A1a). The two beams of light are then recombined to form a single beam and the

630   interference is recorded on a detector as an interferogram. Height difference on a surface or

631   changes in height due to surface retreat or advancement with time are observed as a change from

632   destructive to constructive interference, e.g. black to white in the interferogram.

633   As the direct information about changes in height can only be obtained from the shift in the

634   fringes on an interferogram (seen as a sharp change from black to white) rather than the whole

635   image, three normal interferograms were collected every 30 seconds for several hours using a

636   mega-pixel Peltier-cooled CCD camera with an acquisition rate of >1s by shifting the reference

637   mirror using a piezo actuator to 0, $2/3\pi$ and $4/3\pi$ phase positions. A phase image (Fig. A1b),

638   from which any pixel of the image can provide quantitative data, was then calculated from the

639 normal interferograms for each time step by determining the intensity of the fringe at a point x,y

640 (I_n) for each phase shifting position using $I_n = a(x, y) + b(x, y) \cos[\varphi(x, y) + \delta_n]$.

641 Where a is the background, b the amplitude of the fringe wavelet, φ the phase and δ_n the phase

642 shift for position n. The intensity from the three interferograms was then combined by cancelling

643 the other independent variables at each intensity of the conventional interferogram to produce the

644 contrast in the phase image, ϕ, using

645
$$\phi(x, y) = \arctan\left(\frac{\sqrt{3}\left[I_3(x, y) - I_2(x, y)\right]}{2I_1(x, y) - I_2(x, y) - I_3(x, y)}\right).$$

646 In the phase image (Fig. A1b) the change in fringe contrast from dark to light is due to changes in

647 height at the surface.

648 The interferometer is isolated from external vibrations by an air-suspended optical table and is

649 located in a temperature controlled clean-room, however, the sensitivity of the measurements to

650 other disturbances such as stage vibration, cell distortion etc. means an internal reference surface

651 was required. Gold nanoparticles were deposited on the surface as a suspension in deionized

652 water followed by fast drying of the sample so that the nanoparticles stuck to the surface. The

653 stability of the nanoparticles was evident from their ability to remain attached to the surface

654 during the flow-through experiments and their effectiveness as reference material in previous

655 studies (van Driessche et al., 2011). Vertical movement recorded by these particles during the

656 measurements was subtracted from the vertical movement of the surface to reduce the influence

657 of disturbances. During data analysis several different gold particles were examined to ensure

658 that the gold nanoparticles remained fixed during the experiment and therefore height oscillations

659   due to variations in temperature etc. were subtracted efficiently. The gold particle that produced

660   the minimal amount of noise in the corrected data was chosen for further data analysis.

661   After being corrected for drift, the acquired data was batch processed as described by Satoh et al.

662   (2007) to produce time-space diagrams of the change in grayscale intensity (I) with time along a

663   specific line in the phase image (Fig. A1c). Due to the monochromatic processing of the data the

664   raw data files were converted from a 24-bit bitmap file format to an 8-bit grayscale image

665   resulting in contrast values between 0 and 255 in the images. Changes in grayscale intensity (Δz)

666   at a specific point with time were taken directly from the time-space diagrams taking the

667   refractive index of the solution (n_r) into account using

668
$$v(x, y) = \frac{\Delta z(x, y)}{\Delta t} = \frac{\lambda_{522}}{2n_r} \times \frac{\Delta I(x, y)}{255}$$

669   (Fig. A1d, Table 1) and plotted as a graph to determine the vertical velocity $v(x, y)$.

670   The velocity of vertical retreat $v(x,y)$ was translated into the more typical dissolution rates

671   (mol/cm^2/s) using rate= $-v$(x,y)/V_m (Table 2), where V_m is the molar volume of forsteritic olivine

672   (4.39x10^{-5} m^3/mol) taken from the RRUFF database for Sapat olivines (RRUFF ID R060551).

673   The vertical retreat rates were normalized to step density, surface slope, by calculating the step

674   retreat using v_{step} = $-v$(x,y)/tanθ, where $v(x,y)$ is the vertical velocity and Θ the measured angle of

675   the surface slope.
