24 **Abstract**

25 Sulfate minerals are important indicators for aqueous geochemical environments. The
26 geology and mineralogy of Mars have been studied through the use of various remote-sensing
27 techniques, including thermal (mid-infrared) emission and visible/near-infrared reflectance
28 spectroscopies. Spectral analyses of spacecraft data (from orbital and landed missions) using
29 these techniques have indicated the presence of sulfate minerals on Mars, including Fe-rich
30 sulfates on the iron-rich planet. Each individual Fe-sulfate mineral can be used to constrain bulk
31 chemistry and lends more information about the specific formational environment (e.g., Fe²⁺
32 sulfates are typically more water soluble than Fe³⁺ sulfates and their presence would imply a
33 water-limited (and lower Eh) environment; Fe³⁺ sulfates form over a range of hydration levels
34 and indicate further oxidation (biological or abiological) and increased acidification). To enable
35 better interpretation of past and future terrestrial or planetary data sets, with respect to the Fe-
36 sulfates, we present a comprehensive collection of mid-infrared thermal emission (2000 to 220
37 cm⁻¹; 5-45 μm) and visible/near-infrared (0.35-5 μm) spectra of 21 different ferrous- and ferric-
38 iron sulfate minerals. Mid-infrared vibrational modes (for SO₄, OH, H₂O) are assigned to each
39 thermal emissivity spectrum, and the electronic excitation and transfer bands and vibrational OH,
40 H₂O, and SO₄ overtone and combination bands are assigned to the visible/near-infrared
41 reflectance spectra. Presentation and characterization of these Fe-sulfate thermal emission and
42 visible/near-infrared reflectance spectra will enable the specific chemical environments to be
43 determined when individual Fe-sulfate minerals are identified.

52

53 **1. Introduction**

54 The 370-390 sulfate-mineral species (Hawthorne et al., 2000; Athena Mineralogy URL,
55 <http://athena.unige.ch/athena/mineral/minppcl6.html>) are indicators of aqueous environments,
56 and can form over a broad range of geochemical conditions. Through evaluation of the chemical
57 formulae of these numerous sulfate species, we determined that approximately 25% of known
58 sulfate minerals are Fe-bearing (Fe^{3+} , Fe^{2+}). Fe^{3+} sulfate minerals tend to form in acidic
59 environments at a range of temperatures, through precipitation due to evaporation of
60 concentrated sulfuric acid solutions (e.g., H_2SO_4) such as may occur in volcanic
61 hydrothermal/fumarolic/aerosol or acid mine drainage environments; conversely, many Fe^{2+}
62 sulfates form at higher pH, in neutral to alkaline hydrothermal environments. Fe-bearing sulfates
63 occur not only on Earth, but there is strong evidence for Fe-bearing sulfates occurring on Mars as
64 well (e.g., Burns 1987). Fe^{2+} sulfates that form in a less oxidizing environment have been
65 identified on Mars, and there is a great likelihood that szomolnokite (and/or other Fe^{2+} sulfates)
66 (Bishop et al. 2009; Weitz et al. 2012) would be widespread because the martian environment is
67 enriched in iron and sulfur (specifically dominated by Fe^{2+} -bearing primary igneous minerals and
68 sulfate). There is visible/near-infrared (VNIR) spectral evidence for a broad distribution of the
69 similarly structured mono-hydrated sulfate species, kieserite, which is in solid solution with
70 szomolnokite (e.g., Arvidson et al. 2005; Gendrin et al. 2005; Bishop et al. 2009; Murchie et al.
71 2009; Roach et al. 2009). Fe^{3+} sulfates also have been identified on Mars as jarosite in the Ca-,
72 Mg-sulfate outcrops in Terra Meridiani using Mössbauer spectroscopy (Klingelhofer et al. 2004;
73 Morris et al. 2006), and as ferricopiapite, fibroferrite, hydronium jarosite, (para)butlerite;
74 (para)coquimbite, rhomboclase, or yavapaiite in yellowish/whitish light-toned soils in Gusev
75 Crater using VNIR and thermal infrared (TIR) spectroscopy (Johnson et al. 2007; Lane et al.

76 2008; Wang and Ling 2011). These light-toned soils were exposed serendipitously in the *Spirit*
77 rover tracks by a broken, dragging wheel (Figure 1) and may be extensive across Mars, although
78 buried in subsurface materials. The fine-grained dust on Mars also may contain hydrous Fe-
79 bearing sulfate minerals (Lane et al. 2004; Bishop et al. 2005) that could act as agents for
80 cementing the particles in the martian duricrusts (Binder et al. 1977; Mutch et al. 1977; Jakosky
81 and Christensen 1986).

82 Within the Fe-bearing subgroup of the almost 400 terrestrial sulfates, we determined the
83 majority (~87%) are hydrated with OH (~10%), H₂O (~44%), or both (~33%). Hence, these Fe-
84 bearing sulfates, along with other hydrated minerals, may host the H₂O that has been identified at
85 low and middle latitudes through measurement of hydrogen by the Gamma Ray Spectrometer
86 (GRS) and the Neutron Spectrometer (NS) that were flown on the Mars Odyssey spacecraft
87 (Boynton et al. 2002; Feldman et al. 2002, 2004; Bish et al, 2003; Wang et al. 2008;
88 Karunatillake et al., 2012). Hydrated Fe-sulfates can hold up to 50 wt.% H₂O in their structures.
89 On Mars, the close association of H₂O and S, and the H₂O:S molar ratio (between 2.4 and 4.0)
90 for 80% of the martian mid-latitudes (bulk regolith to decimeter depths) can be explained more
91 simply by the presence of Fe-sulfates rather than by Ca- or Mg-sulfates or other mineral phases
92 such as phyllosilicates or zeolites, thus affirming the importance and potential of Fe sulfates as a
93 hydrated mineral in the martian subsurface (Karunatillake et al., 2012, 2013).

94 Previously Lane (2007) published thermal infrared (TIR) (mid-infrared) emissivity
95 spectra of 37 various sulfates, only eight of which were Fe-bearing in their classical formulation.
96 Here we continue that work, with the objective of presenting thermal emissivity spectra (2000 to
97 220 cm⁻¹; 5 to 45 μm), as well as VNIR reflectance spectra (0.35-5 μm), of a larger suite of Fe-
98 bearing sulfates. This collection of Fe-sulfate spectra will permit better analyses of previously

99 acquired and future thermal emission and visible/near-infrared reflectance data, enabling a more
100 thorough understanding of the geology of Mars (as well as Earth and other planetary bodies
101 when similar remote-sensing techniques are utilized). The TIR and VNIR spectra presented in
102 this work are available as supplementary material to this paper in the Mineralogical Society of
103 America's online depository.

104

105 **2. Sample Descriptions**

106 For this study 21 iron-bearing sulfate mineral samples were studied (Table 1). These
107 include the mineral species amarantite, beaverite, botryogen-Zn, butlerite, copiapite/
108 ferricopiapite, coquimbite/paracoquimbite, goldichite, hydronium jarosite, jarosite, kornelite,
109 magnesiocopiapite, natrojarosite, parabutlerite, rhomboclase, römerite, rozenite, sideronatrite,
110 slavikite, szomolnokite, voltaite, and yavapaiite.

111 Many Fe sulfates occur together making spectral measurements on natural samples
112 difficult. To obtain the highest-quality, nominally one-phase laboratory spectra, the sulfate
113 mineral samples were coarsely crushed, hand-picked, and sieved in a best-attempt to purify the
114 sample, and then were analyzed by X-ray diffraction (XRD) to identify the mineral and any other
115 phases present. During the drawn-out collection and culling phase of the samples, various XRD
116 analyses were conducted at Franklin and Marshall College, Indiana University, and the
117 University of Western Ontario. These samples were also the subjects of a parallel Mössbauer
118 study (Dyar et al. 2014).

119 The hand-picked samples were sieved to particle sizes of <45 μm , 45-125 μm , and >125
120 μm (or 125-250 μm). Although all of the samples were measured by each technique, generally,
121 the TIR emissivity spectra of the coarsest samples are presented here in order to emphasize the

122 fundamental bands (i.e., increased spectral contrast) and minimize volume scattering effects
123 (e.g., Lyon 1964; Aronson et al. 1966; Hunt and Vincent 1968; Hunt and Logan 1972; Aronson
124 and Emslie 1973; Salisbury and Eastes 1985; Salisbury and Wald 1992; Moersch 1992; Hapke
125 1993; Moersch and Christensen 1995; Mustard and Hays 1997; Lane 1999) . The coarsest
126 particle-size sample was used unless a high-quality, pure, single-mineral spectrum was obtained
127 from the solid hand sample (chips or chunks) prior to sieving and hand-picking, or a pressed
128 pellet was made from the finest particulate sample after the XRD and VNIR data were obtained.
129 Pellets were formed using a standard Carver hydraulic 13 mm press and die. Pressing the fine-
130 grained samples into optically thick pellets (discs) eliminated the volume scattering effects from
131 the spectra. Note that only sulfate powder was pressed into the pellets; no other substrate was
132 included (e.g., KBr that is used for a transmission technique using pellets). The VNIR reflectance
133 spectra of generally the finest-particle samples are presented because of their increased sample
134 reflectance and enhanced spectral features.

135

136 **3. Experimental Methods**

137 **Thermal Infrared Emission Spectroscopy:** The samples in this study were analyzed for
138 thermal emission at ambient pressure using Arizona State University's Mars Space Flight
139 Facility. The spectrometer used is a modified Nicolet Nexus 670 E.S.P. FT-IR interferometer
140 attached to an external glove box containing a temperature-stabilized sample chamber
141 (maintained with circulating water behind the chamber wall). It is equipped with a
142 thermoelectrically stabilized deuterated triglycine sulfate (DTGS) detector and a CsI beam
143 splitter that allow the measurement of emitted radiation over the mid-infrared range of 2000 to
144 220 cm^{-1} (5 to 45 μm). To reduce and maintain the amount of atmospheric H_2O and CO_2 vapor

145 inside the spectrometer, external sample chamber, and glove box (and to reduce the degradation
146 of the hydrophilic CsI beam splitter) the entire system is continuously purged with air scrubbed
147 of H₂O and CO₂.

148 Each sample in a sample cup was placed into the sample chamber of the spectrometer and
149 heated to a sustained temperature, on average, of 50 °C to minimize the loss of structural H₂O
150 and maintain the sulfate coordination. The samples were kept warm by actively heating the
151 sample cups during the data acquisition period of 160 or 270 scans at 2 cm⁻¹ sampling while their
152 passively emitted radiation was measured. Each sample was measured several times and spectra
153 were summed for better signal-to-noise and to produce a representative average spectrum.
154 Additional details of the data calibration are presented in Christensen and Harrison (1993),
155 Wenrich and Christensen (1996), and Ruff et al. (1997).

156

157 **Visible, Near Infrared Reflectance Spectroscopy:** Reflectance spectra were acquired at
158 Brown University's RELAB facility. Bidirectional spectra were collected for the samples relative
159 to halon using a VNIR spectrometer from 0.3 to 2.5 μm at 5 nm spectral sampling under ambient
160 conditions using a standard configuration (incidence = 30°; emission = 0°), then corrected for the
161 absolute reflectance of the halon. Additional reflectance spectra were measured from 1-50 μm
162 using a biconical Nicolet FTIR spectrometer in a controlled, dry environment relative to a rough
163 gold surface as in previous studies (Bishop and Murad 2005). The infrared spectra were
164 measured with 2 cm⁻¹ spectral sampling in an environment purged of H₂O and CO₂ for 10-12
165 hours. Composite, absolute reflectance spectra were prepared by scaling the FTIR data to the
166 bidirectional data near 1.2 μm.

167

168 4. Obtained Spectra and Assignment of the Bands

169 **TIR Emissivity Data:** Sulfate minerals may be distinguished using thermal infrared
170 (mid-infrared) spectroscopy because each crystal structure and specific chemical composition
171 produce a distinct spectrum as a result of the fundamental vibrational modes of the crystal
172 structure and their associated overtones and combination bands. Mid-infrared sulfate mineral
173 spectra are dominated by the vibrational behavior of the S-O bonds in the sulfate anion, and in
174 some cases, influenced by the presence of OH or H₂O, or even CO₃, in the structure. Early mid-
175 infrared spectroscopic studies showed that the aqueous sulfate anion (SO₄²⁻) produces four
176 infrared absorption features at ~1105, ~983, ~611, and ~450 cm⁻¹ corresponding to the
177 asymmetric stretch, ν₃; symmetric stretch, ν₁; asymmetric bend, ν₄; symmetric bend, ν₂,
178 respectively (Nakamoto 1986; also see Herzberg 1945; Hug 1997), of which only ν₃ and ν₄ are
179 infrared active. These vibrations are modified from simple T_d site symmetry when the sulfate
180 anion is present within a solid-state medium, such as a mineral with a repeating molecular
181 structure. Cation complexation of SO₄²⁻ causes distortions of the sulfate polyhedra (e.g., Griffen
182 and Ribbe 1979), resulting in the potential appearance of all four sulfate vibrational modes (i.e.,
183 band splitting / removal of degeneracy) in the spectrum due to lowered symmetry (e.g., Ross
184 1962; Steger and Schmidt 1964; Hezel and Ross 1966; Brown and Ross 1970; Chio et al 2004;
185 Makreski et al. 2005; Lane 2007; Majzlan and Michallik 2007; Hyde et al. 2011; Apopei et al.
186 2012). In a solid-state sulfate mineral, internal vibrational features generally appear at ~1050-
187 1250 (ν₃), ~1000 (ν₁), ~500-700 (ν₄), and ~400-500 (ν₂) cm⁻¹ (e.g., Herzberg 1945; Nakamoto
188 1986; Vassallo and Finnie 1992; Bishop and Murad 2005; Lane 2007; Hyde et al. 2011), and at ~
189 <550 cm⁻¹ due to lattice vibrations (e.g., Serna et al. 1986; Clark 1999; Lane 2007), including
190 metal-oxygen, librational and translational modes that occur at lower wavenumbers, respectively.

191 The ν_2 band is known to be significantly weaker than the ν_1 mode and commonly is not
192 observable in the infrared spectra of sulfates (Hezel and Ross 1966). Additional bands may
193 appear in the emissivity spectra due to the presence of H₂O or hydroxyl in the crystal structure.
194 These features include H₂O bending (δ H₂O) modes (Omori and Kerr 1963; Ross 1974), and
195 metal-OH in-plane (δ) and out-of-plane (γ) bending modes (e.g., Libowitzky 1999; Majzlan et al.
196 2011). Note that the spectral band positions mentioned above and presented in this work are the
197 locations of the features on the emissivity spectra, not the frequencies of oscillators used in
198 dispersion theory.

199 Most sulfate minerals consist of SO₄ tetrahedra polymerized to various degrees with MO₆
200 polyhedra (where M is a cation), providing an organizational basis for the crystal structure
201 descriptions in Hawthorne et al. (2000). Their structural organization is borrowed for this paper
202 as well.

203

204 **VNIR Reflectance Data:** Early reflectance spectra of sulfates in the VNIR region
205 demonstrated that the dominant bands near 1.4-1.5 and 1.9-2.0 μm are due to H₂O (Hunt et al.
206 1971). More recent VNIR studies covered additional sulfate minerals and showed that both OH
207 and H₂O are responsible for most features in the 1-3 μm range (e.g., Clark et al. 1990; Crowley
208 1991; Bishop and Murad 1996; Bishop and Murad 2005; Cloutis et al. 2006; Hyde et al. 2011);
209 however, features near 4.3-5.3 μm are attributed to overtones and combinations of the ν_3 SO₄
210 vibration (Blaney and McCord 1995; Bishop and Murad 2005; Hyde et al. 2011). VNIR
211 reflectance spectra have been presented in recent studies for some Fe sulfates but spectra of
212 many of these cover only the spectral range of 0.4-2.5 μm and the hydration state of the sample
213 was not always certain: rozenite, rhomboclase, voltaite, halotrichite, coquimbite/paracoquimbite,

214 copiapite/ferricopiapite, amarantite, jarosite, fibroferrite, sideronatrite, botryogen, and
215 szomolnokite (Crowley et al. 2003; Lane et al. 2004; Bishop and Murad 2005; Bishop et al.
216 2005; Cloutis et al. 2006). The current study presents VNIR reflectance spectra, coordinated with
217 the mid-IR data and mineral structure, for high-purity and well-characterized samples.
218 Schwertmannite is often classified as a sulfate mineral, but is actually an Fe oxyhydroxide
219 mineral similar to akaganeite (Bigham et al. 1994) and is not included in this study.
220 Schwertmannite has sulfate groups present as anions inside the structural tunnels and exhibits
221 spectral properties similar to ferrihydrite (Bishop and Murad 1996).

222 Optical absorption bands are observed from 0.4 to ~1.2 μm for Fe-bearing sulfate
223 minerals (Burns 1993). Many Fe sulfates exhibit a sharp but weak band near 0.43 μm due to the
224 ${}^6\text{A}_{1g}$ to (${}^4\text{A}_{1g}$, ${}^4\text{E}_g$) electronic excitation transition (Crowley et al. 2003; Bishop and Murad 2005;
225 Cloutis et al. 2006). An additional electronic band occurs near 0.5-0.6 μm in many Fe sulfate
226 spectra due to the ${}^6\text{A}_{1g}$ to ${}^4\text{T}_{2g}$ transition that generally results in a shoulder in VNIR reflectance
227 spectra but is occasionally observed as a band (Crowley et al. 2003; Bishop and Murad 2005;
228 Cloutis et al. 2006). The ${}^6\text{A}_{1g}$ to ${}^4\text{T}_{1g}$ electronic transition can occur over a wider wavelength
229 range, from ~0.77 to 0.93 μm (Crowley et al. 2003; Bishop et al. 2005; Bishop and Murad 2005;
230 Cloutis et al. 2006). The Fe^{2+} crystal field band occurs at longer wavelengths, near 0.9-1.2 μm
231 (Burns 1993; Cloutis et al. 2006).

232

233 **4.1. Finite Clusters of SO_4 Tetrahedra and MX_6 Octahedra**

234 The minerals in this structure group (Figures 2a, b) are comprised of finite clusters of SO_4
235 tetrahedra and MX_6 octahedra, where X is an unspecified ligand (such as H_2O or OH), and the
236 structural groups are linked through hydrogen bonding (see Hawthorne 1985).

237 **Coquimbite/paracoquimbite:** The structures of coquimbite and its polytype
238 paracoquimbite are based on layers of $[\text{Fe}_3(\text{SO}_4)_6]$ clusters (whose long axis is parallel to $[001]$),
239 isolated $\{\text{Fe}(\text{H}_2\text{O})_6\}$ octahedra, and H_2O groups. The $\text{Fe}(\text{H}_2\text{O})_6$ octahedra are connected into
240 sheets by hydrogen bonding. The coquimbite/paracoquimbite sample studied here is well
241 crystalline and contains approximately subequal amounts of the two minerals as determined by
242 XRD. The sample spectrum (Figure 2a) shows two clear ν_3 features at 1180 and 1100 cm^{-1} ; the
243 shape of the 1100- cm^{-1} band suggests that there may be another weaker ν_3 band at slightly lower
244 frequency, in contrast to the three bands seen in the transmission data of Moenke (1962 as
245 reported by Ross 1974). A strong ν_1 feature is present at 1013 cm^{-1} . Three ν_4 bands occur at 685,
246 650, and 597 cm^{-1} ; however, the 685- cm^{-1} band is very small but distinct in this very clean
247 spectrum. The ν_2 features occur at 480 and 443 cm^{-1} with strong lattice modes occurring at <350
248 cm^{-1} . The bands that result from the H_2O in the coquimbite structure can be seen at ~ 890 and 816
249 cm^{-1} (bending modes) and the $\delta\text{H}_2\text{O}$ is seen subtly at 1690 cm^{-1} .

250 **Römerite:** Römerite contains Fe^{2+} that coordinates with six H_2O molecules and Fe^{3+} that
251 binds four H_2O molecules and two oxygen anions in different SO_4 groups. As such, the structure
252 of römerite is based also on isolated $\{\text{Fe}(\text{H}_2\text{O})_6\}$ octahedra and $[\text{Fe}(\text{SO}_4)_2(\text{H}_2\text{O})_4]_2$ groups that
253 are weakly connected by hydrogen bonding between the unconnected octahedral and within the
254 latter group (Fanfani et al. 1970; Hawthorne et al. 2000). In römerite (Figure 2a), the H_2O in the
255 structure appears as an emissivity maximum at ~ 1673 cm^{-1} . There are three clear ν_3 features
256 occurring at 1139, 1078, and 1035 cm^{-1} with another subtle shoulder bump that may be a
257 possible ν_3 at ~ 1168 cm^{-1} . A strong ν_1 feature occurs at 996 cm^{-1} and 2 possible ν_4 features can
258 be seen at ~ 658 and ~ 593 cm^{-1} . It is possible that a H_2O libration feature occurs as a small band

259 at 815 cm^{-1} . A ν_2 feature occurs at $\sim 477\text{ cm}^{-1}$. A strong lattice mode is present, but the band is
260 truncated on the long-wavelength side, so the position of its deepest point is unknown.

261 **Rozenite:** The structure of rozenite (ferrous iron only) is comprised of $[\text{Fe}_2(\text{SO}_4)(\text{H}_2\text{O})_8]$
262 clusters that are solely hydrogen bonded together, both within and between the clusters
263 (Hawthorne et al, 2000). The H_2O in rozenite causes an emissivity maximum at $\sim 1680\text{ cm}^{-1}$ (due
264 to the $\delta\text{H}_2\text{O}$ mode), and a band at 818 cm^{-1} and weaker bands at ~ 760 , 735 , and $\sim 692\text{ cm}^{-1}$ that
265 are attributed to δOH (Figure 2a). Rozenite exhibits a deep ν_3 feature at 1100 cm^{-1} and two small
266 shoulder features at ~ 1013 and $\sim 1220\text{ cm}^{-1}$ that also are representative of the ν_3 bands. The ν_1
267 band appears at 992 cm^{-1} . The rozenite spectrum shows a fairly broad ν_4 band centered at ~ 602
268 cm^{-1} with two other ν_4 bands that appear as subtle shoulders on the higher frequency side at ~ 660
269 and $\sim 645\text{ cm}^{-1}$, and a possible ν_2 band at $\sim 468\text{ cm}^{-1}$.

270

271 **VNIR Reflectance Data:** The coquimbite spectrum exhibits three Fe^{3+} excitational
272 absorptions at 0.43 , 0.56 , and $0.78\text{ }\mu\text{m}$ (similar to bands observed for coquimbite by Bishop et al.
273 2005 and Cloutis et al. 2006), while the rozenite spectrum has a sharp band at $0.43\text{ }\mu\text{m}$ and a
274 broad Fe^{2+} excitational absorption centered near $1.0\text{ }\mu\text{m}$ with a shoulder near $1.2\text{ }\mu\text{m}$ (similar to
275 features seen by Crowley et al. 2003 and Bishop et al. 2005). The römerite spectrum contains a
276 shoulder near $0.5\text{ }\mu\text{m}$, Fe^{3+} bands near 0.85 and $0.91\text{ }\mu\text{m}$ with a broad shoulder out to $\sim 1.17\text{ }\mu\text{m}$
277 due to Fe^{2+} (Figure 2b).

278 The coquimbite and römerite spectra have similar NIR vibrational bands; both include a
279 weak band/shoulder at $1.45\text{ }\mu\text{m}$ and a weak band at $\sim 1.78\text{ }\mu\text{m}$. A strong H_2O doublet, due to
280 stretching plus bending combination vibrations, is found at 1.93 and $2.01\text{ }\mu\text{m}$ for römerite and
281 1.94 and $1.98\text{ }\mu\text{m}$ for coquimbite. A shoulder feature due to H_2O is found near $2.55\text{ }\mu\text{m}$ for

282 römerite, and the H₂O stretching vibration occurs near 2.75-3 μm. A doublet near 2.49 and 2.57
283 μm is observed in coquimbite, along with a strong H₂O stretching vibration near 2.9-3.1 μm that
284 has completely saturated the spectrum. The rozenite spectrum exhibits H₂O overtone and
285 combination bands centered at 1.4 and 1.9 μm, respectively. A doublet is observed at 2.42 and
286 2.53 μm, a strong broad H₂O stretching vibration is seen from 2.9-3.2 μm, and a set of SO₄
287 overtones and combinations occurs from 4.2-4.9 μm.

288

289 **4.3. Infinite chains of SO₄ tetrahedra and MX₆ octahedra**

290 The minerals in this structure group (Figures 3a-e) are comprised of infinite chains of
291 SO₄ tetrahedra and MX₆ octahedra, and the chains often are parallel to the *c* axis of the mineral
292 (see Hawthorne, 1985).

293 **Amarantite:** The amarantite structure is based on two octahedra that edge-share (a
294 dimer) with an additional two octahedra that attach to the dimer, making a tetramer (Figure 3a).
295 Further, two sulfate tetrahedra attach to this tetramer to form a [Fe₂O(H₂O)₄(SO₄)₂] chain and
296 provide additional linkages to other tetramers comprising more complex chains (Süsse 1968;
297 Hawthorne et al. 2000). With the additional H₂O, the amarantite formula may be written as
298 [Fe₂O(H₂O)₄(SO₄)₂](H₂O)₃.

299 The emissivity spectrum of amarantite is shown in (Figure 3a). The bending mode of the
300 H₂O in the structure is seen at ~1642 cm⁻¹, whereas asymmetric SO₄ stretching modes occur at
301 ~1215 (as a shoulder), 1154, 1090, and 1059 cm⁻¹. There is a small doublet in the spectrum that
302 may represent both the δOH mode at 1018 cm⁻¹ and the ν₁ band at 1004 cm⁻¹. However, if the
303 doublet is really just jagged due to noise, then the middle of that band would be at ~1009 cm⁻¹
304 and would likely represent just the ν₁ band. Other features include two small bands at 804 and

305 $\sim 748 \text{ cm}^{-1}$ for the δOH modes; ν_4 modes occur at ~ 645 , 595 , and $\sim 528 \text{ cm}^{-1}$; the ν_2 mode band is
306 at 463 cm^{-1} . A long-wavelength band is present at $\sim 289 \text{ cm}^{-1}$ as well as a truncated band.

307 **Botryogen-Zn:** In botryogen, the infinite chains of Fe-centered octahedra are linked to
308 SO_4 tetrahedra, to which Zn-centered octahedra attach through one of the tetrahedral vertices
309 (Figure 3a). This structure is represented as $[\text{ZnFe}(\text{OH})(\text{H}_2\text{O})_6(\text{SO}_4)_2](\text{H}_2\text{O})$. Interchain linkages
310 are present exclusively through hydrogen bonding (Hawthorne 1985; Hawthorne et al. 2000).
311 The botryogen-Zn emissivity spectrum (Figure 3a) has many bands for this complex, monoclinic
312 salt, due to the presence of OH and H_2O in the structure and its low symmetry. The ν_3 bands
313 occur at 1220 , 1132 , and 1031 cm^{-1} with additional ν_3 bands at 1164 (shoulder) and 1068 cm^{-1} .
314 These five ν_3 bands exhibited in zincobotryogen are comparable to the five ν_3 bands shown for
315 botryogen in the transmission data of Moenke (1962) as assigned by Ross (1974). The ν_1 band is
316 small but clear at 999 cm^{-1} . It is possible that the small band at 1010 cm^{-1} is due to H_2O in the
317 mineral (δOH) because it occurs just to the high-frequency side of the ν_1 band, similar to the
318 same band relationship in jarosite to be discussed below. A small feature at 805 cm^{-1} also could
319 result from an OH bending vibration. Constituent H_2O additionally causes a bending mode
320 ($\delta\text{H}_2\text{O}$) to be seen at 1660 cm^{-1} (Ross 1974). Three strong ν_4 bands are present at 602 , 545 , and
321 485 cm^{-1} , with a broad, less-defined band at $\sim 655 \text{ cm}^{-1}$. The ν_2 band may occur at $\sim 393 \text{ cm}^{-1}$ and
322 there is a strong lattice band at $\sim 280 \text{ cm}^{-1}$.

323 **Butlerite/parabutlerite:** In butlerite/parabutlerite, infinite chains of
324 $[\text{Fe}(\text{OH})(\text{H}_2\text{O})_2(\text{SO}_4)]$ are linked solely by hydrogen bonding, and there are no interstitial cations
325 (Hawthorne et al. 2000) (Figure 4a). In the butlerite spectrum (Figure 3a), the H_2O in the
326 structure appears as an emissivity maximum at $\sim 1688 \text{ cm}^{-1}$. There is a clear ν_3 feature at 1123
327 cm^{-1} with other subtle ν_3 shoulder bumps at ~ 1200 and $\sim 1045 \text{ cm}^{-1}$; the ν_1 feature occurs at 992

328 cm^{-1} . The bands at 1013 and 806 cm^{-1} are due likely to δOH modes. Four ν_4 features can be seen
329 at 694, 657, 592, and 506 cm^{-1} . The bands at 441 and ~ 413 may be ν_2 bands, and there is a strong
330 lattice band at ~ 252 cm^{-1} but the noise in the data confuses the position and it may be a truncated
331 band whose true position is masked by the jaggedness of the spectrum at the lower
332 wavenumbers. The spectrum of the parabutlerite sample (Figure 3a) is very similar to that of
333 butlerite and offers an example of sample-to-sample variations that may arise in the spectra. As
334 in butlerite, for parabutlerite the H_2O deformation mode occurs at ~ 1688 cm^{-1} and the δOH mode
335 at 1013 cm^{-1} . The ν_3 features occur at 1233, 1176, 1098, 1054, and 1024 cm^{-1} and the ν_1 mode is
336 found at 997 cm^{-1} . Other bands seen at 650, 602, 503, and ~ 476 cm^{-1} represent the ν_4 modes.
337 Bands at 446 and ~ 330 cm^{-1} may be ν_2 modes and lattice modes may occur at ~ 256 cm^{-1} and as a
338 deep, but truncated, band.

339 **Copiapite/ferricopiapite and Magnesiocopiapite:** Majzlan and Michallik (2007)
340 describe the structure of the copiapite group minerals as a combination of infinite chains of
341 $[\text{Fe}_4(\text{SO}_4)_6(\text{H}_2\text{O})_8(\text{OH})_2](\text{H}_2\text{O})_2$ and slabs of $\{[M(\text{H}_2\text{O})_6](\text{H}_2\text{O})_4\}$, where M is Fe^{3+} in copiapite
342 and Mg^{2+} in magnesiocopiapite. The charge difference requires subtle structural variations.
343 Emissivity spectra of copiapite and magnesiocopiapite are shown in Figure 3a, and it can be seen
344 that their spectra are quite similar. The largest difference occurs because the magnesiocopiapite
345 sample was measured as a pressed pellet, whose resulting spectrum was less noisy, with deeper
346 spectral features than the copiapite spectrum. Also, the magnesiocopiapite spectrum shows a
347 distinct δOH band that is not evident in the copiapite spectrum (except perhaps as a subtle
348 shoulder on the ν_1 band).

349 Specifically, the copiapite spectrum exhibits ν_3 bands at ~ 1212 , ~ 1109 , and 1047 cm^{-1} .
350 The ν_1 clearly occurs at 998 cm^{-1} . The ν_4 bands are found at ~ 603 and ~ 542 cm^{-1} . The ν_2 band is

351 exhibited at $\sim 410\text{ cm}^{-1}$ and a strong lattice mode is truncated so its actual position is unclear. The
352 $\delta\text{H}_2\text{O}$ and δOH features are seen at ~ 1662 and $\sim 790\text{ cm}^{-1}$, respectively. In magnesiocopiapite,
353 the bands are as follows: the H_2O deformation mode ($\delta\text{H}_2\text{O}$) occurs at $\sim 1656\text{ cm}^{-1}$, the ν_3 bands
354 are at 1213, 1146 (a shoulder), 1107, 1049, and possibly a shoulder at 1031 cm^{-1} . The ν_1 band is
355 found at 997 cm^{-1} with a distinct δOH feature at 1013 cm^{-1} . Three ν_4 bands are seen at 639, 595,
356 and 556 cm^{-1} , and a ν_2 band is present at 414 cm^{-1} . A final band may occur at $\sim 262\text{ cm}^{-1}$;
357 however, this band may be affected by noise and is also truncated so its position is uncertain.

358 **Sideronatrite:** This mineral species is based on infinite octahedral-tetrahedral chains that
359 show considerable disorder in relation to the adjacent chains in their structure (Figure 3a). The
360 backbone structure consists of infinite chains of $[\text{Fe}(\text{SO}_4)_2(\text{OH})]^{2-}$ that align parallel to the c axis
361 (Scordari and Ventruti 2009; Scordari et al. 2010; Della Ventura et al. 2013) that are crosslinked
362 by Na-distorted octahedra in which each Na atom is linked to four oxygen atoms and two H_2O .
363 Hydrogen bonding to the infinite chains is provided through these water molecules. The
364 sideronatrite crystal structure and thermal emissivity spectrum of this pelletized sample are
365 shown in Figure 3a. The pelletized sample produced a clean spectrum that shows the H_2O
366 deformation mode as an emissivity minimum at $\sim 1637\text{ cm}^{-1}$. Many ν_3 features are apparent,
367 including those at 1270 (small), 1217, 1208, 1139, 1112 (shoulder), 1068, and 1034 cm^{-1} . A
368 sharp ν_1 feature occurs at 997 cm^{-1} ; however, this deep feature's shape indicates that a δOH
369 feature may be overlapping, or that this is the primary δOH feature and a ν_1 may be overlapping;
370 Della Ventura et al. (2013) identify two bands here at 997 and 981 cm^{-1} but assign them both to a
371 ν_1 splitting. Other distinct features (representing ν_4) are found at 666, 650, 634, 620, 609, and a
372 very deep band at 519 cm^{-1} ; Della Ventura et al. (2013) attribute this band to ν_2 . This deep band
373 alternatively may be assigned to γOH . Bands at 409 and 400 cm^{-1} represent ν_2 modes, and the

374 lowest wavenumber bands (typically metal-oxygen or lattice modes) are seen at 308 and ~265
375 cm^{-1} and a deep, truncated band.

376

377 **VNIR Reflectance Data:** The amaranтите spectrum contains an Fe^{3+} excitation at 0.87
378 μm that is also seen in botryogen at 0.93 μm , and in butlerite/parabutlerite at 0.92 μm (Figure
379 3b). Copiapite and Mg-copiapite spectra both have an Fe^{3+} band at 0.88 μm that also occurs in
380 the sideronatrite spectrum at 0.94 μm (Figure 3c).

381 There are numerous narrow NIR bands in sideronatrite that are attributed to H_2O and OH
382 near 1.45, 1.91, 1.99, 2.27, 2.5, 2.8, and 2.95 μm . Additional bands in the 4-5 μm region are
383 consistent with overtones and combinations of the SO_4 vibrations (Figure 3c). The many doublet
384 and triplet features observed in the sideronatrite spectrum indicate that these bands have been
385 split, probably due to multiple H_2O and OH sites in the mineral structure. Similar features were
386 observed in sideronatrite spectra by Cloutis et al. (2006). The NIR spectra of amaranтите,
387 botryogen, and copiapite all exhibit H_2O bands near 1.45, 1.95, and 2.8-3.2 μm . The H_2O
388 stretching overtone near 1.4 μm and combination band near 1.9 μm both occur as a doublet for
389 amaranтите, botryogen, butlerite, and parabutlerite: at 1.447 and 1.478, and at 1.944 and ~1.98
390 μm in spectra of amaranтите (related to those observed by Cloutis et al. 2006), at 1.447 and 1.480,
391 and at 1.929 and 1.960 μm in spectra of botryogen (similar to those observed by Cloutis et al.
392 2006), at 1.476 and 1.503, and at 1.960 and 2.026 μm in spectra of butlerite, and at ~1.48 and
393 ~1.50, and at 1.961 and ~2.03 μm in spectra of parabutlerite. The butlerite and parabutlerite also
394 have OH combination stretching plus bending vibrations at 2.24 and 2.28 μm (Figure 3b). Each
395 of these spectra includes SO_4 overtones and combinations over the range ~4.2-4.8 μm .

396 Shown in Figures 3d,e are examples of spectra of three particle sizes of the amaranthite
397 and botryogen samples, respectively. The spectral brightness in the VNIR region is brighter for
398 the finer particle-size samples and there are some differences in band depth, but no changes are
399 evident in the band center. For this paper we are focusing on the band centers and, hence, are
400 presenting only the VNIR reflectance spectra of the fine particle-size fractions.

401

402 **4.4. Infinite sheets of $M_3(\text{OH})_6(\text{SO}_4)_2$**

403 The minerals in this structure group (Figures 4a, b) are comprised of infinite
404 $[M_3(\text{OH})_6(\text{SO}_4)_2]$ sheets.

405 **Beaverite:** The rhombohedral structure of beaverite (Figure 4a) consists of tetrahedral-
406 octahedral-tetrahedral sheets that lie perpendicular to the c axis. The Fe-centered octahedra are
407 linked along the sheet with OH groups. The two remaining OH-attached vertices along the c axis
408 connect the octahedral layer to sheets of SO_4 tetrahedra that also lie perpendicular to the c axis.
409 Beaverite is a member of the alunite-jarosite group (Breidenstein et al. 1992); however, its
410 spectrum (Figure 4a) is somewhat dissimilar to those of alunite or jarosite. This sample was
411 pelletized and produced a low-noise spectrum that shows the H_2O deformation mode as an
412 emissivity minimum at $\sim 1602 \text{ cm}^{-1}$. The ν_3 bands are seen at 1163, 1110, and possibly 984 cm^{-1} .
413 The ν_1 occurs at 1001 cm^{-1} and there appears to be a δOH at 1019 cm^{-1} . An additional δOH is at
414 $\sim 735 \text{ cm}^{-1}$. A strong ν_4 band is seen at 625 cm^{-1} with two smaller ν_4 bands at 604 and 575 cm^{-1} .
415 Following the spectral character of jarosite described in detail below, the beaverite spectrum
416 shows a ν_2 band at 423 cm^{-1} . Strong metal-oxygen lattice modes occur at 512 and 469 cm^{-1} and
417 another is seen as a large truncated band.

418 **Jarosite, Hydronium Jarosite, Natrojarosite:** The structure of the jarosite-group
419 minerals (Figure 4a) may be described as a series of layers formed by tetrahedral-octahedral-
420 tetrahedral sheets that lie perpendicular to the *c* axis. In the sheets made of Fe-centered
421 octahedra, the Fe atoms are linked through hydroxyl groups (Serna et al. 1986). The tetrahedral
422 (SO₄) sheets are joined by the cations (e.g., K in jarosite, H₃O in hydronium jarosite, and Na in
423 natrojarosite) that are found at the center of polyhedra surrounded by six oxygen atoms and six
424 OH groups) (Basciano and Peterson 2008). The mid-infrared spectra of jarosite, hydronium
425 jarosite, and natrojarosite are presented in Figure 4a. Their similar structures cause their
426 emissivity spectra to be remarkably similar as well.

427 The jarosite spectrum was taken of a solid jarosite coating on a host rock. The jarosite
428 emissivity spectrum exhibits two ν_3 bands at 1220 and 1112 cm⁻¹, a ν_1 band at 1006 cm⁻¹, and a
429 single ν_2 at 445 cm⁻¹. This spectrum shows a subtle shoulder at ~662 cm⁻¹ on a stronger feature at
430 635 cm⁻¹ suggesting two ν_4 bands. Additional modes of jarosite are shown to occur at ~1020
431 (due to δ OH) and 524, 476, ~336, and ~242 cm⁻¹ due to Fe-O lattice modes. The broader lattice-
432 mode band at 524 cm⁻¹ suggests a possible superposed γ OH mode on the higher frequency side
433 of the feature as observed by both Serna et al. (1986) and Sasaki et al. (1998). An emissivity
434 maximum at 1633 cm⁻¹ results from δ H₂O (e.g., Omori and Kerr 1963).

435 Hydronium jarosite differs from jarosite by the replacement of K⁺ with H₃O⁺ in its
436 structure. The hydronium jarosite analyzed in this study was not a pure endmember because
437 XRD peaks were shifted slightly, suggesting minor substitution of H₃O⁺ by another cation (e.g.,
438 K⁺ or Na⁺). The hydronium jarosite spectrum is of much lower quality than the jarosite spectrum
439 (that was a well-formed coating on a host rock) or the natrojarosite spectrum (that was taken of a
440 pressed pellet). This noise makes the identification of the band position much less accurate;

441 however, the best determinations are as follows. The H₂O bending mode ($\delta\text{H}_2\text{O}$) is found at
442 $\sim 1651\text{ cm}^{-1}$, the asymmetric SO₄ stretching modes occur at ~ 1220 and 1121 cm^{-1} , the ν_1 band lies
443 at $\sim 997\text{ cm}^{-1}$, and the δOH band is shown at 1033 cm^{-1} . Three uncertain bands at 898, 845, and
444 $\sim 760\text{ cm}^{-1}$ may represent additional δOH modes. The ν_4 modes occur at 675 and 635 cm^{-1} , and
445 the ν_2 mode bands are at 428 and 393 cm^{-1} . Other *M-O* or lattice modes occur at ~ 526 , 475, and
446 $\sim 336\text{ cm}^{-1}$, and an additional long-wave band is present at $\sim 265\text{ cm}^{-1}$ but that may just be the
447 local bottom of the feature due to noise and its true position is truncated.

448 Natrojarosite differs from jarosite by the replacement of K⁺ with Na⁺ in its structure. For
449 the natrojarosite sample, we measured a pressed pellet. The emissivity spectrum (Figure 4a) of
450 natrojarosite shows the H₂O deformation mode ($\delta\text{H}_2\text{O}$) to occur at $\sim 1635\text{ cm}^{-1}$ (e.g., Omori and
451 Kerr 1963); the ν_3 bands are seen at 1200 and 1107 cm^{-1} . The small ν_1 band occurs at $\sim 1010\text{ cm}^{-1}$
452 and a δOH feature is found at 1026 cm^{-1} . Two ν_4 bands are seen at ~ 666 and 632 cm^{-1} , and a ν_2
453 band is present at 441 cm^{-1} . Other distinct bands occur at 524, 478, and 327 cm^{-1} with a possible
454 additional band at 347 cm^{-1} . A large truncated band also is apparent in the spectrum.

455 Spectral comparison shows the positions of the bands in all of the jarosite-group minerals
456 to be generally similar (Figure 4a; Table 2), with a few notable exceptions. In natrojarosite, the
457 ν_4 bands are split more broadly than for jarosite, which exhibits only a single feature with a
458 shoulder (Lane 2007). The same bands in hydronium jarosite are spaced even farther apart. Also,
459 the ν_2 feature in natrojarosite is at just slightly lower frequency than in jarosite, but the ν_2 feature
460 in hydronium jarosite occurs at $\sim 15\text{ cm}^{-1}$ lower wavenumber than in the other two jarosite-group
461 minerals.

462

463 **VNIR Reflectance Data:** Crystal field bands are observed for the jarosite type minerals
464 near 0.43, 0.65 and 0.91 μm (Figure 4b; Bishop and Murad, 2005). The ${}^6\text{A}_{1g}$ to (${}^4\text{A}_{1g}$, ${}^4\text{E}_g$)
465 transition was observed at 0.435 μm in the spectra of all three jarosite samples in this study. This
466 feature was observed at 0.436 μm in a jarosite spectrum presented in Crowley et al. (2003), at
467 0.435-0.437 μm in the jarosite spectra of Bishop and Murad (2005), and at 0.43-0.436 μm in
468 jarosite spectra obtained by Cloutis et al. (2006). The ${}^6\text{A}_{1g}$ to ${}^4\text{T}_{2g}$ transition is observed as a
469 shoulder in jarosite spectra and it is thus difficult to assign a wavelength for this absorption. It
470 was estimated here to be near 0.65 μm , which is in agreement with the 0.64-0.66 μm found
471 previously for jarosite (Bishop and Murad, 2005). The ${}^6\text{A}_{1g}$ to ${}^4\text{T}_{1g}$ transition was observed at
472 0.907 μm in the spectrum of our jarosite, at 0.915 μm in the spectrum of our hydronium jarosite,
473 and at 0.922 μm in the spectrum of our natrojarosite. This transition was identified at 0.924 μm
474 by Crowley et al. (2003), at 0.90-0.925 μm by Bishop and Murad (2005), and at 0.915-0.922 μm
475 by Cloutis et al. (2006). Slight variations in the shoulder near 0.65 and width of the 0.91-0.92 μm
476 band for the natrojarosite spectrum compared with the other jarosite type spectra could be due to
477 particle size, as the 45-125 μm size fraction was analyzed for the natrojarosite sample because
478 insufficient <45- μm material was available. This transition is observed as a doublet at 0.755 and
479 0.890 μm in the beaverite spectrum.

480 Additional NIR bands are observed near 1.47, 1.85, 2.22 (shoulder), 2.26, 2.41 (weak),
481 2.47 (weak), 2.51, and 2.62 μm due to overtones and combinations of the OH vibrations (Figure
482 4b; Bishop and Murad 2005). For the jarosite spectrum in our study these features are observed
483 at 1.469, 1.849, 2.264, 2.507, and 2.620 μm . For the hydronium jarosite spectrum they are found
484 at 1.470, 1.846, 2.268, 2.516, and 2.620 μm , for the natrojarosite spectrum they occur at 1.476,
485 1.847, 2.267, 2.516, and 2.620 μm and for the beaverite spectrum they are much weaker and

486 occur near 1.472, 1.865, 2.289, 2.516, and ~2.64 μm . The hydronium jarosite also exhibits an
487 H_2O stretching plus bending combination band at 1.94 μm . Weaker features are observed for the
488 jarosite and natrojarosite samples due to small amounts of adsorbed H_2O . The beaverite spectrum
489 includes a weak, broad H_2O combination band near 2.05 μm and a rounded $\text{H}_2\text{O}/\text{OH}$ feature near
490 3 μm . The fundamental OH stretching band includes multiple overlapping vibrations and occurs
491 near 2.937 μm for jarosite, 2.953 μm for hydronium jarosite, and 2.946 μm for natrojarosite. A
492 number of small bands are also observed between 4.5-4.9 μm that are assigned to either an
493 overtone of the $\text{SO}_4 \nu_3$ vibration or an overtone of the OH bending vibration (Bishop and Murad
494 2005).

495

496 **4.5. Infinite sheets of SO_4 tetrahedra and MX_6 octahedra**

497 **Goldichite:** The structure of goldichite (Rosenzweig and Gross 1954) is based on
498 corrugated sheets of $[\text{Fe}(\text{SO}_4)_2 \cdot 2 \text{H}_2\text{O}]$ clusters that link corner-shared octahedra and tetrahedra.
499 These sheets are connected by 9-coordinated K atoms and additional water molecules (i.e.,
500 hydrogen bond linkages) (Graeber and Rosenzweig 1971; Hawthorne 1985; Hawthorne et al.
501 2000) (Figure 5a). The spectrum of goldichite (Figure 5a) shows that constituent H_2O causes a
502 bending vibration ($\delta\text{H}_2\text{O}$) at $\sim 1640 \text{ cm}^{-1}$; three ν_3 bands occur at 1258, 1169, and 1119 cm^{-1} , and
503 the ν_1 band is seen at 997 cm^{-1} . The ν_4 bands are at 689, 627, and 597 cm^{-1} ; the ν_4 bands are at
504 476 and 428 cm^{-1} . Lattice modes occur at 359 cm^{-1} and in a band that is truncated at the edge of
505 the spectrum.

506 **Kornelite:** The structure of kornelite (Figure 5a) is based on corrugated sheets of
507 octahedral-tetrahedral layers of $[\text{Fe}_2(\text{H}_2\text{O})_6(\text{SO}_4)_3]$ attached to H_2O groups in the interlayer that
508 provide hydrogen bonding for linking the sheets (Robinson and Fang 1973; Hawthorne et al.

509 2000; Majzlan et al. 2005; Ackermann et al. 2009). The H₂O deformation band appears in the
510 emissivity spectrum (Figure 5a) at ~1665 cm⁻¹ (albeit weakly) and a H₂O libration mode is seen
511 at 751 cm⁻¹ according to a comparable assignment by Ling and Wang (2010). Four ν₃ features
512 are seen at 1206 (as a shoulder), 1160, 1121, and 1054 cm⁻¹. A ν₁ feature is apparent at 1020 cm⁻¹.
513 The ν₄ features occur at 627 and 593 cm⁻¹ with a possible additional band at 650 cm⁻¹ and the
514 ν₂ features occur at 492 and 448 cm⁻¹. Unfortunately, the spectrum does not extend to lower
515 wavenumbers below 400 cm⁻¹ due to an operational error with the spectrometer.

516 **Rhomboclase:** The structure of rhomboclase is based on [Fe(H₂O)₆(SO₄)₃] groups with
517 additional interstitial (H₅O₂) groups that provide extensive hydrogen bonding (Hawthorne et al
518 2000). For rhomboclase, the bands in the emissivity spectrum (Figure 5a) are as follows: the H₂O
519 deformation mode (δH₂O) at ~1585 cm⁻¹ (weak), and ν₃ bands at ~1210 (a shoulder), 1180, 1068
520 (a shoulder), and at 1043 cm⁻¹. The ν₁ band occurs at 1022 cm⁻¹ with a δOH at 745 cm⁻¹. Two ν₄
521 bands are seen at 664 cm⁻¹ and as a small band at ~627 cm⁻¹. A possible γOH feature is found at
522 593 cm⁻¹; a ν₂ band occurs at ~485 cm⁻¹; and a lattice mode occurs at 308 cm⁻¹ along with a
523 lattice mode that is a truncated band so the actual position is not determined.

524 **Slavikite:** Slavikite is based on a sheet of corner-sharing octahedra and tetrahedra
525 (Hawthorne et al. 2000) of [Fe₅(H₂O)₆(OH)₆(SO₄)₆] that form into honeycomb-like structures
526 (Parafiniuketal et al. 2010) (Figure 5a). Holes in the open sheet are occupied by Na and H₂O
527 groups. The interlayer consists of {Mg(H₂O)₆} octahedra and disordered SO₄ tetrahedra that are
528 bound by hydrogen bonds. Although there are broad regions of reduced emission, this sample did
529 not produce a spectrum with clear, distinct features, even after pelletizing and deepening the
530 spectral features. Unfortunately, the overall sample size was so small that the pellet was really
531 just a thin (<<1 mm) chip about 5x7 mm² in area, so it could not produce a quality spectrum.

532 Nonetheless, the features that are discernible include: the broad H₂O deformation feature at
533 ~1612 cm⁻¹, ν₃ bands at 1199 and ~1084 cm⁻¹, a ν₁ band at ~1000 cm⁻¹, and ν₄ and ν₂ bands at
534 597 and 462 cm⁻¹, respectively. There is a clear lattice-mode band, but it is truncated so its
535 position is unknown.

536 **Yavapaiite:** The structure of yavapaiite consists of sheets of [Fe(SO₄)₂] stacked in the *c*
537 axis direction and linked together by coplanar layers of 10-coordinated K atoms (Hawthorne
538 1985; Hawthorne et al. 2000). This configuration leads to perfect {001} cleavage (Graeber and
539 Rosenzweig 1971). For our work, we pressed a synthetic yavapaiite powder into a pellet to get a
540 spectrum devoid of volume scattering effects. As expected for a nominally anhydrous mineral,
541 our emissivity spectrum (Figure 5a) does not show any strong δH₂O, δOH, or γOH modes. The
542 ν₃ modes occur at 1254, ~1142 (as a shoulder), and 1024 cm⁻¹. No obvious ν₁ mode is seen at
543 lower wavenumbers than the ν₃ features, so it may be that the ν₁ mode lies within the ν₃ features
544 and is therefore unseen. This possibility is supported by the transmission spectrum of yavapaiite
545 shown in Forray et al. (2005) with four distinct features in the ~1000-1300 cm⁻¹ range (likely
546 three ν₃ bands and a ν₁ feature). In our emissivity spectrum there also are distinct features at 676,
547 620, and 588 cm⁻¹ that represent the ν₄ bands. The ν₂ bands are seen at 469, 444, and possibly
548 416 and 370 cm⁻¹. The 370 cm⁻¹ band may be a metal-oxygen or lattice mode, plus there is
549 another longwave band that is truncated, but whose position may be at 255 cm⁻¹. Yavapaiite is
550 the anhydrous form of goldichite, and generally the yavapaiite bands (ν₃, ν₄, ν₂) appear at
551 smaller wavenumbers (i.e., lower frequencies) than the bands exhibited in the more-hydrous
552 goldichite. This trend is opposite that presented by Lane (2007) for the Ca-sulfate and Mg-sulfate
553 suites.

554

555 **VNIR Reflectance Data:** The crystal field bands vary widely for the sulfate minerals
556 with infinite sheets of SO₄ tetrahedra and MX₆ octahedra (Figure 5b) indicating a variety of Fe
557 sites for this mineral group. The goldichite spectrum exhibits only a very weak, broad Fe³⁺ ⁶A_{1g}
558 to ⁴T_{1g} transition band centered near 0.89 μm that is consistent with a very low Fe content. The
559 kornelite spectrum has Fe³⁺ bands at 0.55 and 0.76 μm due to the ⁶A_{1g} to ⁴T_{2g} transition and ⁶A_{1g}
560 to ⁴T_{1g} transition, respectively, which are similar to those of coquimbite, but otherwise unusual
561 for Fe sulfates or oxides. Thus, these bands are good spectral indicators for the presence of
562 kornelite or coquimbite. The rhomboclase spectrum includes a sharp Fe³⁺ ⁶A_{1g} to (⁴A_{1g}, ⁴E_g)
563 transition at 0.430, a ⁶A_{1g} to ⁴T_{2g} transition at ~0.5 (shoulder), and ⁶A_{1g} to ⁴T_{1g} transition at 0.800
564 μm, similar to features observed by Crowley et al. (2003). The slavikite spectrum includes a
565 small sharp band at 0.43 μm and a broad band centered near 0.87 μm indicating a distribution of
566 the Fe³⁺ sites. The yavapaiite spectrum has Fe³⁺ bands at 0.425, ~0.52 (shoulder), and 0.735 μm.
567 The NIR spectrum of goldichite exhibits multiple doublet and triplet features akin to that
568 of sideronatrite, indicating splitting of the H₂O bands. The most prominent H₂O bands in the
569 goldichite spectrum occur at 1.426, 1.478, 1.768, 1.906, 2.169, 2.210, 2.320, 2.514 and 2.84 μm.
570 The kornelite spectrum contains weak H₂O bands at 1.16, 1.42, 1.92, 1.98 (broad), and 2.75 μm
571 and a completely saturated H₂O stretching band near 2.8-3.5 μm, whereas the rhomboclase
572 spectrum has a weak broad H₂O band near 1.25 μm followed by a drop in reflectance near 1.53
573 μm, a H₂O combination band near 2.0 μm, shoulders near 2.43 and 2.58 μm, and a weak, broad
574 H₂O stretching band near 2.8-2.95 μm. The NIR spectrum of slavikite somewhat resembles that
575 of gypsum with a triplet at 1.446, ~1.49, and 1.553 μm, a broad shoulder at 1.75 to 1.78 μm, a
576 strong combination band at 1.943 with a shoulder near 1.97 μm, a weak band at 2.12 μm, a
577 doublet at 2.224 and 2.266 μm, shoulders near 2.43 and 2.55 μm, and a strong, broad H₂O band

578 near 2.8-3.5 μm . Yavapaiite is anhydrous and its spectrum does not contain any H_2O vibrational
579 bands in the NIR region.

580 The yavapaiite spectrum exhibits multiple, strong SO_4 overtones and combinations from
581 4-5 μm . The dominant bands occur at 4.05, 4.12, 4.42, 4.52, 4.73, and a doublet at 4.88 and 4.92
582 μm . The goldichite spectrum includes multiple weak bands from \sim 4.2-4.9 due to SO_4 overtones
583 and combinations. The slavikite spectrum has a broad strong band centered near 4.5 μm and
584 another at 4.73 μm . The reflectance is very low for rhomboclase and kornelite spectra in the 3-5
585 μm region and sulfate bands are not observed for these minerals.

586

587 **4.6. Infinite frameworks of SO_4 tetrahedra and MX_6 octahedra**

588 **Szomolnokite:** The mineral szomolnokite is a monohydrated sulfate and it is the Fe-
589 endmember in a solid solution series with the Mg-endmember kieserite (Jambor et al. 2000).
590 Pure szomolnokite contains only Fe^{2+} cations and has a networked structure with $[\text{Fe}(\text{SO}_4)(\text{H}_2\text{O})]$
591 chains that are cross-linked with other similar chains by corner sharing between octahedra and
592 tetrahedra of neighboring chains (Figure 6a). The szomolnokite hand sample is well crystalline
593 and provided strong features in the emissivity spectrum (Figure 6a). The szomolnokite spectrum
594 closely resembles a kieserite emissivity spectrum (Lane 2007); however, the szomolnokite
595 spectral features are shifted to longer wavelengths by 20-100 wavenumbers. The internal
596 vibrational bands due to the sulfate anion are distinct in the spectrum and consist of three ν_3
597 bands at 1226, 1195, and 1149 cm^{-1} . The ν_1 band appears as a small feature at 1018 cm^{-1} .
598 Features at 626, 606, and 554 cm^{-1} result from the ν_4 vibrations. The feature at 361 cm^{-1} is a ν_2
599 mode, but its assignment is uncertain. The truncated band at \sim 275 likely is due to a Fe-O
600 vibration.

601 In addition, there is a pronounced feature at 846 cm^{-1} that is uncommon in most sulfates
602 but is seen otherwise only in kieserite (at 919 cm^{-1}) (Lane 2007), among all the other sulfates
603 studied to date by the authors. This unusual feature is likely to appear also in a spectrum of
604 szmikite (a monohydrated Mn-sulfate of similar crystal structure), but to date a good sample has
605 not been obtained for analysis. This uncommon band likely is due to the unusual librational
606 mode (rocking) of the H_2O molecule seen in kieserite-group minerals but not in other hydrates in
607 which H_2O molecules form a similar coordination (Soptrajanov and Trpkovska 1993; Grodzicki
608 and Piszczek 1998). The presence of this band is a reliable indicator of monohydrated kieserite-
609 group sulfates (Lane 2007).

610 **Voltaite:** The structure of voltaite is more complex than that of many other Fe sulfates
611 and was determined by Mereiter (1972). The Fe^{2+} - and Fe^{3+} -containing structure consists of a
612 continuous framework of $[\text{Fe}^{3+}\text{O}_6]$ octahedra, $[\text{Fe}^{2+}_{5/6}\text{Fe}^{3+}_{1/6}\text{O}_4(\text{H}_2\text{O})_2]$ octahedra, and $[\text{KO}_{12}]$
613 polyhedra linked by (SO_4) tetrahedra. This structural arrangement allows disordered $[\text{Al}(\text{H}_2\text{O})_6]$
614 octahedra to occupy the structure as well (Ertl et al. 2008) (Figure 6a). The voltaite emissivity
615 spectrum (Figure 6a) exhibits a H_2O deformation feature at $\sim 1670\text{ cm}^{-1}$ but the broadness of the
616 feature makes the position uncertain. The ν_3 bands occur at 1171, ~ 1123 (shoulder), 1050, and
617 979 cm^{-1} (shoulder); the ν_1 feature occurs at 1004 cm^{-1} . The δOH bands are not sharp or strong
618 but possibly are at ~ 832 and $\sim 735\text{ cm}^{-1}$. The ν_4 bands are seen at 671 (subtle), 625, 584, and 520
619 cm^{-1} ; ν_2 bands are seen at 469, 444, and possibly 416 cm^{-1} . Long-wave metal-oxygen/lattice
620 modes are seen at 370 cm^{-1} (possibly) and as a deep feature at 255 cm^{-1} , but the latter feature is
621 truncated and the spectral noise may mask the true position of this feature.

622

623 **VNIR Reflectance Data:** The crystal field bands are quite different for szomolnokite and
624 voltaite (Figure 6b). The szomolnokite spectrum includes a pair of Fe²⁺ bands something like that
625 observed for pyroxene (e.g., Cloutis and Gaffey 1991). The Fe²⁺ electronic excitation bands are
626 centered near 0.94 and 1.33 μm in the spectrum of our szomolnokite sample, and at 0.93 and
627 1.31 μm in a szomolnokite spectrum analyzed by Crowley et al. (2003). The spectrum of voltaite
628 has an Fe³⁺ electronic transition near 0.62 μm.

629 The voltaite spectrum exhibits H₂O features at 1.439, 1.719, 1.940, ~2.4, ~2.50, and 2.8-
630 3.5 μm, similar to other polyhydrated sulfates such as copiapite, römerite, and amarantite.

631 Szomolnokite is a monohydrated sulfate and its spectrum has very different H₂O bands, more
632 similar to those of kieserite (Bishop et al. 2009). The H₂O bands in the szomolnokite spectrum
633 occur at 1.520 μm for the H₂O stretching overtone, at 2.098 μm for the stretching plus bending
634 combination band, at 2.403 and 2.624 μm for additional H₂O bands, and a strong H₂O stretching
635 band occurs at ~2.9-3.3 μm.

636 The voltaite spectrum has an additional band at 4.0 μm and several weak bands from 4.5-
637 5 μm in the SO₄ overtone and combination band region, including absorptions at 4.82 and 4.96
638 μm. The szomolnokite spectrum includes multiple weak bands from 4.2-4.9 μm; the most
639 prominent bands are present at 4.34, 4.58, 4.70, 4.81, and 4.94 μm.

640

641 **5. Implications**

642 **5.1 Crystal structure**

643 Sulfate minerals are based on a repeated ordering of SO₄ tetrahedra polymerized with
644 MO₆ polyhedra (where *M* is a cation), and a majority of all sulfates (including Fe sulfates) are
645 hydrous (OH, H₂O). Of the 21 iron sulfates presented here, only one (yavapaiite) is nominally

646 anhydrous. Thermal emission spectra exhibit features related to the vibrational behavior and
647 interaction of the molecules within the sulfate mineral, and as such, their crystal structures
648 influence the character of their spectra. The figures in this paper are arranged by grouping
649 mineral spectra according to their molecular structure following the organization of Hawthorne
650 et al. (2000). This grouping should allow spectral similarities related to structure to stand out.

651 Cation complexation of the sulfate tetrahedron (that would not be deformed in its aqueous
652 state and would exhibit T_d site symmetry) causes distortions of the sulfate and changes the
653 symmetry to C_{3v}/C_3 (monodentate, corner-sharing), C_{2v}/C_2 (bidentate binuclear, edge-sharing),
654 or C_1/C_s (bidentate binuclear, multidentate, corner-sharing, edge-sharing) (Myneni 2000). This
655 reduced symmetry causes band splitting, hence, the lower the symmetry of the sulfate, the more
656 additional features will be seen in the spectra (e.g., Adler and Kerr 1965; Myneni 2000).

657 Comparison among the sulfate emissivity figures shows that *all* the spectra are dominated
658 by deep bands related to the ν_3 vibrational modes that occur in the ~ 980 to 1270 cm^{-1} spectral
659 region and by a deep band(s) (beginning at $\leq 380\text{ cm}^{-1}$), often truncated at the low-wavenumber
660 limit of our data related to M -O bonds or lattice vibrations (or H_2O libration). In addition to these
661 two deep band regions, the spectra of sulfates with sheets of $M_3(\text{OH})_6(\text{SO}_4)_2$ (the
662 beaverite/jarosite group, Figure 4a) exhibit a third region of deep bands (~ 460 - 580 cm^{-1}) that are
663 approximately equivalent in depth to their ν_3 bands. The other structural groups do not exhibit
664 that behavior, but rather show weaker bands (ν_4, ν_2) in the spectral region between the ν_3 and the
665 long-wave (oft-truncated) bands.

666 Inspection of each iron sulfate structural group individually (i.e., each figure separately)
667 shows general spectral similarity within each iron sulfate mineral group. For example, in Figure
668 2a, the spectra exhibit a rather dominant, strong single ν_3 band (with other neighboring weaker

669 ν_3 bands). In Figure 3a, the spectra show a grouping of many ν_3 bands that are similarly deep. In
670 Figure 4a, the spectra show the $\nu_3 - \nu_1$ region in each spectrum as two divided groupings of
671 approximately similar-strength bands separated by an emissivity maximum (a flexion position)
672 at $\sim 1050-1075 \text{ cm}^{-1}$ and, as mentioned above, this mineral group has the distinctive
673 characteristic of exhibiting a third deep grouping of bands ($\sim 460-580 \text{ cm}^{-1}$) that are similar in
674 depth to the ν_3 bands. And in Figure 5a, the ν_3 band grouping appears generally somewhat
675 asymmetrical with the deepest feature being on the low-wavenumber side. It is difficult to
676 generalize the spectra in Figure 6a beyond that they have a deep ν_3 band region and a deep long-
677 wave truncated band region; however, that general description would fit all of the sulfate group
678 spectra as mentioned above and is not unique to this structural group.

679 It is clear from this work that although Fe-sulfate minerals are dominated by the same
680 cation (Fe) and share similar structural units of SO_4 tetrahedra and MX_6 octahedra, their various
681 degrees of polymerization and unique crystal structure within their structure classes cause their
682 spectra to differ considerably. On a finer scale, however, the jarosite-series minerals (jarosite,
683 hydronium jarosite, natrojarosite) shown in Figure 4a show that in some cases, if the crystal
684 structure is the same but the cation is varied, the spectra are almost identical with only small
685 variation. Another good example of spectral similarity in sulfates when the crystal structure is
686 the same but the cation differs, lies with the mono-hydrated iron sulfate szomolnokite (Figure 6a)
687 and its Mg-bearing equivalent, kieserite ($\text{MgSO}_4 \cdot \text{H}_2\text{O}$). Lane (2007) showed that the spectra of
688 kieserite and szomolnokite are nearly identical, but the features of szomolnokite are shifted to
689 lower wavenumbers (see Figure 3 in Lane 2007). A final example, but in a different mineral
690 class, is the emissivity spectra of a suite of six-coordinated anhydrous carbonates (see Figure 2 in

691 Lane and Christensen 1997) for which the carbonate spectra all look almost identical, but the
692 fundamental bands are shifted due to the different cation in the crystal structure.

693 Historically, minerals have been grouped in various ways to relate and classify them,
694 such as by Nickel-Strunz groups (into ten primary groups; Strunz and Nickel 2001), Hey's
695 groups (into 32 more-focused groups, Clark 1993), and Dana groups (into 78 very specific
696 groups, Gaines et al. 1997). Investigation of the emissivity spectra shows that the shapes of the
697 Fe-sulfate mineral spectra are best predicted by the Dana class categorization, which is based on
698 structure type. For each mineral species, the Dana number consists of four different numbers
699 separated by periods. The first represents the Dana **class**, which is based on composition or
700 dominant structural elements. There are five classes that include sulfates:

701 Class 28 - Anhydrous Acid and Sulfates (e.g., yavapaiite, 28.03.04.01)

702 Class 29 - Hydrated Acid and Sulfates (e.g., rhomboclase, 29.01.01.01)

703 Class 30 - Anhydrous Sulfates Containing Hydroxyl or Halogen (e.g., jarosite,
704 30.02.05.01)

705 Class 31 - Hydrated Sulfates Containing Hydroxyl or Halogen (e.g., butlerite,
706 31.09.01.01)

707 Class 32 - Compound Sulfates (e.g., burkeite, 2.01.01.01).

708 The second number of the four represents the Dana **type**, which is based on the formula
709 and the number and ratios of cations. The third number represents the mineral **group** (e.g., the
710 alunite group) in which all species have the same structure, and the last number is assigned to the
711 individual **species**. This work has demonstrated that samples in the same group generally have
712 very similar spectra, and samples in the same Dana type are often quite similar as well. For
713 example, kieserite (29.6.2.1) and szomolnokite (29.6.2.2.) are both members of the kieserite

714 group (29.6.2) along with gunningite, dwornikite, poltevinite, szmikite, and cobaltkieserite. It is
715 not necessary to acquire data from all the species in this group to know that their spectra will be
716 similar – although it should be noted that even at the species level, the spectra within a group are
717 not exactly the same and shifted. Rather, they are very similar in spectral shape and shifted, but
718 the fundamental features do not translate exactly. For some spectra, the bands move in opposite
719 directions or at different rates, or some bands merge or vary in other subtle ways, but the overall
720 spectral shape remains distinct. Nonetheless, at this level of classification, the spectra are similar
721 enough that the expert spectroscopist should be able to identify the mineral group and series, and
722 likely the exact mineral species, if that species exists in the spectral database.

723 The VNIR reflectance spectra of the Fe sulfates are highly dependent on the environment
724 of the Fe in the crystal structure and the degree of hydration. The most common crystal field
725 band occurs near 0.78-0.93 μm for Fe^{3+} in sulfates. Additional electronic transitions occur in
726 some minerals as a sharp and usually weak band at 0.43 μm and a shoulder near 0.5-0.65 μm .
727 The spectra of kornelite and coquimbite are unique in that they have two strong crystal field
728 bands near 0.55-0.56 and 0.76-0.78 μm . Fe^{2+} in sulfate spectra exhibit crystal field bands near
729 0.94-1.2 μm and occasionally a second crystal field band at longer wavelengths as in the case of
730 szomolnokite. The H_2O bands are present as smooth, broad bands near 1.45, 1.95, 2.5 and 3 μm
731 in several Fe sulfates such as amaranthite, copiapite, and rozenite. Other Fe-sulfate spectra exhibit
732 H_2O bands that are split into doublets or triplets such as goldichite, slavikite and sideronatrite. Fe
733 sulfates containing OH in their structure such as jarosite and butlerite have spectral features due
734 to OH near 1.42-1.47, 2.2-2.3, and 2.7-2.8 μm . Anhydrous Fe sulfates like yavapaiite do not
735 exhibit spectral features in the range 1-3 μm .

736

737 **5.2 Mars Geochemistry**

738 Many iron sulfate minerals exist both on Earth, often in acid mine drainage (AMD) sites,
739 and on Mars. They form via oxidation of sulfides that can precipitate secondary hydrous oxides,
740 hydroxysulfates, and divalent-metal (M^{2+}) sulfates (e.g., commonly melanterite), and generally
741 lead to the generation of acidic solutions (e.g., Jambor et al. 2000; Jerz and Rimstidt 2005; King
742 and McSween 2005). Although the M^{2+} in sulfates can be Fe, Mn, Co, Ni, Mg, Cu, or Zn,
743 precipitation of Fe-sulfates (followed by Mg-) are dominant in AMD environments (Jambor et al.
744 2000). Further oxidation, dehydration, and/or neutralization will alter the Fe^{2+} sulfates to a wide
745 suite of other Fe^{3+}/Fe^{2+} or exclusively Fe^{3+} sulfates. The presence of Fe sulfates generally implies
746 acidic conditions, so their continued and mineral-specific identification on Mars (e.g.,
747 Klingelhöfer et al. 2004; Wang et al. 2006; Morris et al. 2006; Johnson et al. 2007; Lane et al.
748 2008; Milliken et al. 2008; Bishop et al. 2009) can help aid in the interpretation of the chemical
749 environments and geologic settings in the past and on present-day Mars (e.g., Fe^{2+} sulfates are
750 generally more water soluble than Fe^{3+} sulfates and would imply a water-limited environment;
751 Fe^{3+} sulfates form over a range of hydration levels but are an indication of more oxidation along
752 with low pH, etc.). Each specific Fe-sulfate mineral identification constrains the bulk chemistry
753 and lends more information about the specific formational environment. For example,
754 rhomboclase prefers lower pH (<0) and jarosite prefers a higher pH (2-4) than other Fe-sulfates
755 (e.g., ferricopiapite (pH <2); Majzlan et al. 2006), and yavapaiite is obtainable through thermal
756 decomposition (dehydration) of jarosite (Forray et al. 2005). Dehydration of coquimbite can
757 produce kornelite (Robinson and Fang 1973) that can further dehydrate to pentahydrated Fe^{3+}
758 sulfate (Kong et al. 2011) or rhomboclase (Lane et al. 2008). Rhomboclase also has been seen to
759 hydrate to form kornelite (King, unpublished data) suggesting that the reaction is reversible.

760 Dehydration of melanterite will produce rozenite, which is common on Earth (Kubisz 1960;
761 Kossenberg and Cook 1961; Jambor et al. 2000) and over time in a dry (or higher temperature)
762 environment rozenite (or melanterite) can further dehydrate to szomolnokite (Bolshakov and
763 Ptushko 1971); sometimes the intermediate rozenite is not observed (e.g., Hyde et al. 2011).
764 Long-term paragenesis of Fe³⁺ sulfates in oxidative environments will produce schwertmannite
765 (or jarosite-family minerals if other cations are available) prior to forming Fe oxyhydroxides
766 (Jambor et al. 2000; King and McSween 2005); and there are numerous other examples of how
767 specific formational environments relate to the bulk chemistry and *visa versa*.

768 Oxidation of Fe²⁺ in acid solutions occurs abiologically but also can occur biologically
769 through the presence of oxidizing bacteria such as *Thiobacillus ferrooxidans* (e.g., Lazaroff et al.
770 1982), and Fe³⁺ sulfates depress the freezing point of brines (Chevrier and Altheide, 2008),
771 hence identification of Fe³⁺ sulfates on Mars may be important for selecting future regions of
772 study intended for the study of life on Mars. Finally, Fe sulfates are capable of hosting a
773 significant amount of H₂O in their crystal structures (Table 1) and may be part of the phases in
774 the martian bulk soil that link mineralogy to the amount of water-equivalent hydrogen (WEH)
775 identified by the orbiting Mars Odyssey Gamma Ray Spectrometer (Boynton et al. 2002;
776 Feldman et al. 2002, 2004; Karunatillake et al. 2012, 2013).

777 Not only do specific Fe-sulfate minerals form in specific and predictable chemical
778 environments, but each Fe-sulfate mineral exhibits a unique thermal emissivity and visible/near-
779 infrared spectrum that acts as a spectral fingerprint for that mineral. The Fe-sulfate spectra
780 presented in this work will enable scientists to identify these sulfates on Mars and determine
781 what the chemical environment was on Mars during their formation.

782

783 **Acknowledgments**

784 Thanks are extended to Ferenc Forray for synthesizing the yavapaiite sample, to Brendt
785 Hyde for synthesizing the kornelite sample and doing some XRD measurements, and to Ed
786 Cloutis for the copiapite sample. We thank Phil Christensen for the use of his thermal emission
787 spectrometer laboratory. Additional thanks are extended to reviewers Ed Cloutis and Jeffrey
788 Kargel for their time and effort related to improving this paper. This work (PSI contribution
789 #606) was funded through the NASA Mars Odyssey Participating Scientist Program and the
790 NASA Mars Fundamental Research Program (grant NNX11AF11G). Mertzman thanks NSF for
791 MRI award number 0923224, which funded the purchase of a PANalytical X'Pert Pro X-ray
792 diffractometer equipped with a 15-position sample changer. PLK acknowledges funding from the
793 Canadian NSERC, Canadian Foundation for Innovation, Ontario Innovation Trust and Premier's
794 Research Excellence Award.

1142 Figure 1: Pancam image of the bright soils in the *Spirit* rover tracks in Gusev Crater, Mars,
1143 indicating the presence of Fe sulfates in the subsurface of Mars. A broken, dragging
1144 wheel serendipitously exposed the yellowish/whitish minerals. Image credit:
1145 NASA/JPL/Cornell/Arizona State University

1146 Figure 2a: Mid-infrared thermal emissivity spectra of sulfates with finite clusters of SO₄
1147 tetrahedra and MX₆ octahedra, including their crystal structure diagrams -- coquimbite
1148 (Fang and Robinson 1970), römerite (Fanfani et al. 1970), and rozenite (Baur 1962).
1149 Band depths have been adjusted by multiplying the spectra by the parenthetical amounts;
1150 spectra are then offset for clarity.

- 1151 Figure 2b: VNIR reflectance spectra from 0.4-5 μm of sulfates with finite clusters of SO_4
1152 tetrahedra and MX_6 octahedra including coquimbite/paracoquimbite, römerite, and
1153 rozenite.
- 1154 Figure 3a: Mid-infrared thermal emissivity spectra of sulfates with chains of SO_4 tetrahedra and
1155 MX_6 octahedra, including amarantite, zincobotryogen, butlerite, parabutlerite,
1156 copiapite/ferricopiapite, magnesiocopiapite, and sideronatrite. In addition, the crystal
1157 structure diagrams are shown (amarantite from Süsse 1968; botryogen from Süsse 1967;
1158 butlerite from Fanfani et al. 1971; ferricopiapite from Fanfani et al. 1973; and
1159 metasideronatrite from Ventruti et al. 2010). Band depths have been adjusted by
1160 multiplying the spectra by the parenthetical amounts; spectra are then offset for clarity.
- 1161 Figure 3b,c,d,e: VNIR reflectance spectra of sulfates with chains of SO_4 tetrahedra and MX_6
1162 octahedra including b) amarantite, botryogen, butlerite and parabutlerite, c) copiapite
1163 from 0.4-5 μm , Mg-copiapite, and sideronatrite from 0.4-5 μm , d) three grain size
1164 fractions of amarantite from 0.3-2.65 μm , and e) three particle-size fractions of botryogen
1165 from 0.3-2.65 μm .
- 1166 Figure 4a: Mid-infrared thermal emissivity spectra of sulfates with sheets of $\text{M}_3(\text{OH})_6(\text{SO}_4)_2$,
1167 including beaverite, hydronium jarosite, jarosite, and natrojarosite. In addition, the crystal
1168 structure diagrams for beaverite (Breidenstein et al. 1992) and jarosite (Basciano and
1169 Peterson 2007) are shown. Band depths have been adjusted by multiplying the spectra by
1170 the parenthetical amounts; spectra are then offset for clarity.
- 1171 Figure 4b: VNIR reflectance spectra from 0.4-5 μm of sulfates with sheets of $\text{M}_3(\text{OH})_6(\text{SO}_4)_2$,
1172 including beaverite, jarosite, hydronium jarosite, and natrojarosite. The beaverite
1173 spectrum is offset for clarity.

- 1174 Figure 5a: Mid-infrared thermal emissivity spectra of sulfates with sheets of SO_4 tetrahedra and
1175 MX_6 octahedra, and their crystal structure diagrams -- including goldichite (Graeber and
1176 Rosenzweig 1971), kornelite (Robinson and Fang 1973), rhomboclase (Mereiter 1974),
1177 slavikite (Parafiniuk et al. 2010), and yavapaiite (Graeber and Rosenzweig 1971). Band
1178 depths have been adjusted by multiplying the spectra by the parenthetical amounts;
1179 spectra are then offset for clarity.
- 1180 Figure 5b: VNIR reflectance spectra from 0.4-5 μm of sulfates with sheets of SO_4 tetrahedra and
1181 MX_6 octahedra including rhomboclase, yavapaiite, slavikite, kornelite, and goldichite.
1182 The slavikite spectrum is offset for clarity.
- 1183 Figure 6a: Mid-infrared thermal emissivity spectra of sulfates with frameworks of SO_4 tetrahedra
1184 and MX_6 octahedra, and their crystal structure diagrams -- including szomolnokite
1185 (Wildner and Geister 1991) and voltaite (Mereiter 1972). Spectra are offset for clarity.
- 1186 Figure 6b: VNIR reflectance spectra from 0.4-5 μm of sulfates with frameworks of SO_4
1187 tetrahedra and MX_6 octahedra including szomolnokite and voltaite.

Table 1. Listing of the Fe-sulfate Minerals.

Mineral (XRD character)	Stoichiometric Composition	Sample and Character ^a	Locale
Amarantite (pure)	$\text{Fe}(\text{SO}_4)(\text{OH}) \cdot 3 \text{H}_2\text{O}$	R6254-A ϵ ch; R <45 μm	Sierra Borda, Antofagasta, Chile; Collection of the Smithsonian - National Museum of Natural History
Beaverite (w/ ~5-7% anglesite)	$\text{PbCu}(\text{Fe},\text{Al})_2(\text{SO}_4)_2(\text{OH})_6$	G1241 ϵ pellet; R <150 μm	Unknown
Botryogen-Zn	$(\text{Zn},\text{Mg},\text{Mn})\text{Fe}(\text{SO}_4)_2(\text{OH}) \cdot 7 \text{H}_2\text{O}$	C5525-3 ϵ ch; R <45 μm	Mina Quetena, Calama, Chile; Collection of the Smithsonian - National Museum of Natural History
Butlerite (w/ 5% parabutlerite)	$\text{Fe}(\text{SO}_4)(\text{OH}) \cdot 2 \text{H}_2\text{O}$	VZO108 ^b ϵ pellet; R <45 μm	Borate, Calico Hills, San Bernardino, California
Copiapite ^c (w/ 25% ferricopiapite)	$\text{FeFe}_4(\text{SO}_4)_6(\text{OH})_2 \cdot 20 \text{H}_2\text{O}$	SPT125 ϵ ch; R <45 μm	Sierra Gorda, Chile; Collection of Ed Cloutis
Coquimbite ^d	$\text{Fe}_2(\text{SO}_4)_3 \cdot 9 \text{H}_2\text{O}$	ML-S46 ϵ ch; R <125 μm	Alcaparrosa, Chile
Goldichite (pure)	$\text{KFe}(\text{SO}_4)_2 \cdot 4 \text{H}_2\text{O}$	123922 ϵ ch; R <500 μm	Pozzuoli, Solfatar, Italy; Collection of the Smithsonian - National Museum of Natural History
Hydronium jarosite ^e (+ minor cation)	$(\text{H}_3\text{O})\text{Fe}_3(\text{SO}_4)_2(\text{OH})_6$	R10101 ϵ ch; R <45 μm	Boolcoomatta, South Australia, Australia; Collection of the Smithsonian - National Museum of Natural History
Jarosite (w/ trace unknown)	$\text{KFe}_3(\text{SO}_4)_2(\text{OH})_6$	ML-S51 ϵ ch; R <45 μm	Copiapite Jarosite Mine, Dona Ana Co., NM
Kornelite ^f (pure)	$\text{Fe}_2(\text{SO}_4)_3 \cdot 7 \text{H}_2\text{O}$	ML-S105 ϵ ch; R <45 μm	Synthesized by co-authors PLK and BCH
Magnesiocopiapite (pure)	$\text{MgFe}_4(\text{SO}_4)_6(\text{OH})_2 \cdot 20 \text{H}_2\text{O}$	ML-S86 ϵ pellet; R <45 μm	Alma Pyrite Mine, Leona Heights, Oakland, Alameda Co., CA
Natrojarosite (pure)	$\text{NaFe}_3(\text{SO}_4)_2(\text{OH})_6$	95661 ϵ pellet; R 45-125 μm	Sunset Mining claim near Kingman, AZ
Parabutlerite (pure)	$\text{Fe}(\text{SO}_4)(\text{OH}) \cdot 2 \text{H}_2\text{O}$	157716 ϵ ch; R <45 μm	Chiquicamata, Antofagasta, Chile; Collection of the Smithsonian - National Museum of Natural History
Rhombochase (pure)	$(\text{H}_5\text{O}_2)\text{Fe}(\text{SO}_4)_2 \cdot 2 \text{H}_2\text{O}$	ML-S85 ϵ ch; R <250 μm	Alcaparrosa, Chile
Römerite (pure)	$\text{FeFe}_2(\text{SO}_4)_4 \cdot 14 \text{H}_2\text{O}$	R8415 ϵ >125 μm ; R <45 μm	Near Skauriatissa, Island of Cyprus, Greece; Collection of the Smithsonian - National Museum of Natural History
Rozenite (pure)	$\text{FeSO}_4 \cdot 4 \text{H}_2\text{O}$	JB626-B ϵ ch; R <125 μm	Iron Mountain, CA
Sideronatriite (+ minor phase)	$\text{Na}_2\text{Fe}(\text{SO}_4)_2(\text{OH}) \cdot 3 \text{H}_2\text{O}$	115164 ϵ pellet; R <45 μm	Chiquicamata, Chile; Collection of the Smithsonian - National Museum of Natural History
Slavikite (pure)	$\text{NaMg}_2\text{Fe}_5(\text{SO}_4)_7(\text{OH})_6 \cdot 33 \text{H}_2\text{O}$	140229 ϵ pellet; R 45-125 μm	Valachov, Czech Republic; Collection of the Smithsonian - National Museum of Natural History
Szomolnokite (pure)	$\text{FeSO}_4 \cdot \text{H}_2\text{O}$	104276 ϵ ch; R <45 μm	Tintic Standard Mine, Dividend, UT; Collection of the Smithsonian - National Museum of Natural History

Voltaite (pure)	$K_2Fe_5Fe_3Al(SO_4)_{12} \cdot 18 H_2O$	115035 ϵ ch; R <45 μm	United Verde Mine, Jerome, AZ; Collection of the Smithsonian - National Museum of Natural History
Yavapaiite (pure)	$KFe(SO_4)_2$	ML-S79 ϵ pellet; R <45 μm	Synthesized by Ferenc Forray (Babes-Bolyai U.)

^a Character of sample where ch=chunk/chip(s) or pellet; otherwise particle size fraction is listed for measurements in emissivity (ϵ) or reflectivity (R)

^b VNIR data used sample C5534 (Mina Quetena, Calama, Chile; XRD shows butlerite + minor other phase)

^c Sample SPT125: Cloutis et al, 2006 identify this sample as 90% ferricopiapite/ 10% jarosite

^d Sample ML-S46 contains subequal amounts of coquimbite and paracoquimbite

^e Sample R10101 may contain have some cation substitution (e.g., K^+ or Na^+) for H_3O because the XRD peaks were shifted slightly from those of a hydronium jarosite reference endmember

^f Sample ML-S105 spectrum was corrupted and data from 200 – 400 cm^{-1} were lost

Table 2. Band Assignments of the Fundamental Vibrational Modes in Fe-sulfate Minerals (in cm^{-1}).

Mineral	$\delta\text{H}_2\text{O}$	ν_3	δOH	ν_1	H_2O libration	δOH	ν_4	γOH	ν_2	H_2O libration, M-O, or lattice
