6

7   **Abstract**

8   Iron- and aluminum-bearing $MgSiO_3$ bridgmanite is the most abundant mineral in the

9   Earth's interior; hence its crystal chemistry is fundamental to expanding our knowledge

10   of the deep Earth and its evolution. In this study, the valence and spin state of iron in

11   well characterized Al-free Fe^{3+}-rich bridgmanite were investigated by means of

12   Mössbauer spectroscopy to understand the effect of ferric iron on the spin state. We

13   found that a minor amount of Fe^{3+} is in the low spin state above 36 GPa and that its

14   proportion does not increase substantially with pressure up to 83 GPa. This observation

15   is consistent with recent experimental studies that used Mössbauer and X-ray emission

16   spectroscopy. In the Earth's deep lower mantle, Fe^{3+} spin crossover may take place at

17   depths below 900 and 1200 km in pyrolite and MORB, respectively. However, the

18   effect of spin crossover on physical properties may be small due to the limited amount

19   of Fe^{3+} in the low spin state.

20

21   **Introduction**

22   The crystal chemistry of terrestrial minerals is fundamental to understanding

23   the Earth's interior and its evolution. Iron- and aluminum-bearing $MgSiO_3$ bridgmanite

24   (Bdg) is the most abundant mineral in the Earth's interior and contains a substantial (up

25   to about 20 at. %) amount of iron, which is the fourth most abundant element in the

26   mantle. Bdg can incorporate a substantial amount of Fe^{3+} (e.g., McCammon 1997; Frost

27   et al. 2004), while olivine, the dominant mineral in the upper mantle, accommodates

28   essentially no Fe^{3+} (e.g., McCammon 2005). The substitution of Fe^{3+} for Fe^{2+} has a

29   large influence on physical and chemical properties of Bdg such as elastic constants,

30   iron partition coefficients and electrical/thermal conductivity (Ohta et al. 2010; 2014;

31   Boffa Ballaran et al. 2012; Sinmyo and Hirose 2013; Sinmyo et al. 2014a; Wolf et al.

32   2015; Yoshino et al. 2016). Moreover, both experiments and theoretical calculations

33   suggest that iron in Bdg undergoes spin crossover under deep mantle conditions (Badro

34   et al. 2004; Lin et al. 2012; Potapkin et al. 2013; Mashino et al. 2014). Although iron

35   spin crossover can strongly influence the physical properties of lower mantle minerals,

36   e.g., elastic constants and thermal/electrical conductivity (Lundin et al. 2008; Keppler et

37   al. 2008; Ohta et al. 2010; Catalli et al. 2011), the pressure of spin crossover in Bdg is

38   not well constrained (see reviews by Lin et al. 2013; McCammon et al. 2013 and

39   references therein). Challenges arise due mainly to the presence of iron in two different

40   valence states (Fe^{2+} and Fe^{3+}), and two different sites in the perovskite structure (8-12

41   coordinated A-site and octahedral B-site). Fe^{2+}, which is observed to occupy the A-site,

42   undergoes spin crossover from high spin to intermediate spin (McCammon et al. 2008;

43   Lin et al. 2008; Potapkin et al. 2013), although theoretical calculations do not support

44   the existence of the intermediate spin state of Fe^{2+} (Hsu et al. 2011; Metsue and

45   Tsuchiya 2012). There is general consensus that Fe^{3+} remains in the high spin state to at

46   least 100 GPa when it occupies the A-site (Catalli et al. 2010, 2011; Fujino et al. 2012;

47   Lin et al. 2012; Potapkin et al. 2013; Glazyrin et al. 2014; Kupenko et al. 2014), but

48   undergoes spin crossover from high spin to low spin at 20~60 GPa when it occupies the

49   B-site (Catalli et al. 2010; 2011; Fujino et al. 2012; Lin et al. 2012; Kupenko et al.

50   2015). These observations strongly suggest that the spin crossover pressure is

51   dominantly controlled by Fe^{3+} in the B-site. It has been reported that Fe^{3+} occupies the

52   A-site of Bdg regardless of the oxidation state concentration, Al content and pressure

53   (Kudoh et al. 1990; Vanpeteghem et al. 2006; Glazyrin et al. 2014), while some recent

54   studies have reported that Al-free and Fe^{3+}-bearing Bdg accommodate a detectable

55   amount of Fe^{3+} in the B-site (Catalli et al. 2011; Lin et al. 2012; Hummer and Fei 2012;

56   Kupenko et al. 2015). Since previous studies have investigated Bdg with a limited

57   amount of Fe^{3+}, the electronic state of Fe^{3+} is not well understood, even though the

58   electronic state of iron in Al-free Fe^{3+}-rich Bdg may have a significant effect on the

59   physical/chemical properties of subducted depleted lithospheric mantle with

60   harzburgitic bulk composition (Ringwood 1991). Furthermore, it is recognized that

61   sample synthesis in the diamond anvil cell by laser heating may cause heterogeneity in

62   chemical composition and/or redox state of the sample (e.g., Fialin et al. 2008; Sinmyo

63   and Hirose 2010). Therefore, to minimize the experimental uncertainty, the $Fe^{3+}/\Sigma Fe$

64   ratio of samples pre-synthesized using a large volume press should be characterized

65   before the sample is compressed with a diamond anvil cell. Here, our study aims to

66   explore the spin state of iron under lower mantle conditions by investigating the rarely

67   studied, but well defined Al-free Fe^{3+}-rich Bdg, which provides insight into the complex

68   effects of Al^{3+} and Fe^{3+} on the spin state.

69

70   **Experimental procedure**

71   The sample was synthesized using a multi anvil apparatus. A mixture of fine

72   grained SiO_2 [55.23 wt %] + MgO [37.05 wt %] + $^{57}Fe_2O_3$ (90% enriched) [7.72 wt %]

73   was ground well for about one hour, and then dried at 1273 K in a furnace for one day.

74   We used Fe_2O_3 as a starting material to maximize Fe^{3+} content in the sample. The final

75   mix was loaded into a gold capsule and then packed into a MgO container. The

76   multi-anvil synthesis used $LaCrO_3$ for the heater, and was run for 45 minutes at pressure

77   and temperature conditions of 26 GPa and 1973 K, respectively. The synthesized

78   sample was examined using a field-emission-type scanning electron microscope (SEM)

79   (Leo Gemini 1530) and the chemical composition was determined using an electron

80   microprobe (JEOL JXA-8200) operated at 15 kV and 15 nA. Phase identification was

81   performed by powder X-ray diffraction (XRD) using a FR-D high-brilliance Rigaku

82   X-ray diffractometer with Mo-Kα radiation operated at 55 kV and 60 mA.

83   The high-pressure Mössbauer spectroscopic study was conducted using a

84   diamond anvil cell. Diamonds with 250 μm diameter culets were used as anvils. The

85   polycrystalline sample from the multianvil synthesis was loaded into a hole drilled in a

86   rhenium gasket. Mössbauer spectroscopy was conducted using a nominal 370 MBq

87   [57]Co high specific activity source in a rhodium matrix. The velocity scale was calibrated

88   relative to [57]Fe foil. Mössbauer spectra were analyzed using the MossA software

89   package (Prescher et al. 2012). Mössbauer spectra were collected with increasing

90   pressure up to 83 GPa, and then the pressure was gradually decreased toward ambient

91   conditions.

92

93   **Results**

94   The sample synthesized using the multianvil press was characterized by XRD,

95   Mössbauer spectroscopy and electron microprobe analysis. The electron microprobe

96   analysis yielded a chemical composition of $Mg_{0.971(11)}Fe_{0.064(4)}Si_{0.979(7)}O_3$. The grain size

97   was around 50 μm in diameter. Although a trace amount of quenched liquid material

98   was observed at the very edge of the sample, it was easily removed from the capsule

99   before selecting the Bdg sample for diamond anvil cell experiments. Most likely due to

100   the partitioning of iron between liquid and Bdg, the iron content in the Bdg was

101   depleted in comparison to the starting material. XRD measurements showed that the

102   obtained sample was a single phase of Bdg. The $Fe^{3+}/\Sigma Fe$ ratio of the perovskite was

103   determined to be 0.53(6) according to Mössbauer measurements at ambient conditions.

104   Based   on   this   result,   the   chemical   composition   can   be   described   as

105   $Mg_{0.971}Fe^{2+}_{0.030}Fe^{3+}_{0.034}Si_{0.979}O_3$. The total charge of the cations slightly exceeds six

106   (6.02), which may be due to vacancies in the crystal lattice (Hummer and Fei 2012). A

107   quantitative discussion is not possible, however, since the excess amount (+ 0.3 %) is

108   smaller than the uncertainty in the measurements (~ 1 %).

109   Mössbauer spectra were collected up to 83 GPa at 15 pressure points in total

110   (Fig. 1). The pressure variation of the obtained hyperfine parameters center shift (CS)

111   and quadrupole splitting (QS) are summarized in Figure 2 and Table 1. The spectra at

112   ambient conditions are composed of two components corresponding to Fe^{2+} with higher

113   CS and QS values (hereafter Fe^{2+} #1) and Fe^{3+} with lower CS and QS values (Fe^{3+} #1).

114   The QS values of Fe^{2+} #1 and Fe^{3+} #1 slightly increase with increasing pressure, while

115   their CS values are almost constant (Fig. 2). Above 12 GPa, we observed a component

116   with a high QS value (Fe^{2+} #2), which corresponds to Fe^{2+} in the distorted A-site of Bdg

117   (McCammon et al. 2008; Kupenko et al. 2014). The abundance of Fe^{2+} #2 does not

118   change substantially from 12 to 83 GPa (Fig. 3). At higher pressure, an additional

119   component was observed above 36 GPa (Fe^{3+} #2). This new component exhibits almost

120   zero CS and QS similar to the value for Fe^{3+} #1. These hyperfine parameters are

121   comparable to those of the Fe^{3+} component found in Al, Fe-bearing Bdg at around 40

122   GPa after laser heating (Kupenko et al. 2015). As in the case of the Fe^{2+} #1 and Fe^{3+} #1

123   components, the QS values of Fe^{2+} #2 and Fe^{3+} #2 slightly increase with pressure, in

124   contrast to the constant CS value (Fig. 2). Parallel to the slight increase in abundance of

125   Fe^{3+} #2 with increasing pressure from 40 to 53 GPa, the abundance of Fe^{3+} #1 decreases

126   to compensate, maintaining an essentially constant amount of Fe^{3+} (Fig. 3). The

127   hyperfine parameters vary with pressure in a highly consistent way during compression

128   and decompression (Fig. 2), and the $Fe^{3+}/\Sigma Fe$ ratio refined independently at each data

129   point remains nearly constant throughout the experiment (Fig. 3).

130

131   **Discussion**

132   **Fe^{3+} in Al-free Bdg**

133   It is well known that the $Fe^{3+}/\Sigma Fe$ ratio in Al-bearing Bdg is remarkably high

134   (about 0.5) even under low oxygen fugacity conditions (e.g., McCammon 2005). The

135   high $Fe^{3+}/\Sigma Fe$ ratio can be explained by a coupled substitution mechanism involving

136   Fe^{3+}-Al to Mg-Si in Bdg (Frost et al. 2004; McCammon et al. 2004). In this study, the

137     $Fe^{3+}/\Sigma Fe$ ratio was about 0.5 in the Al-free Bdg synthesized from Fe^{3+}-rich starting

138   material, which is considerably higher than that for Al-free Bdg synthesized from

139   Fe^{2+}-dominant material (Frost et al. 2004 McCammon et al. 2004; Sinmyo et al. 2008).

140   This observation suggests that $Fe^{3+}/\Sigma Fe$ of Al-free Bdg depends on oxygen fugacity as

141   suggested by McCammon et al. (2004). Indeed, Hummer and Fei (2012) and Mashino et

142   al. (2014) reported a $Fe^{3+}/\Sigma Fe$ ratio close to one in Bdg synthesized from Fe^{3+}-rich

143   material. Fe^{3+} #1 most likely occupies the A-site of Bdg because ferric iron mostly

144   occupies the A-site of Bdg at ambient conditions when the ferric iron concentration is <

145 0.04 per formula unit (Hummer and Fei 2012; Sinmyo et al. 2014b). The Fe^{3+} #2

146 component shows moderate QS ~ 1 and low CS ~ 0 (Table 1). These values are

147 consistent with low spin Fe^{3+} in the octahedral sites of the high-pressure phase of

148 FeOOH (Xu et al. 2013), $CaFe_2O_4$ (Greenberg et al. 2013), rare earth orthoferrites with

149 the perovskite structure (Rozenberg et al. 2005), and Al,Fe-bearing Bdg (Kupenko et al.

150 2015). This observation strongly supports the theoretical work of Hsu et al. (2011), who

151 suggested that Fe^{3+} is in the low-spin state in the B-site of Bdg.

152   Pioneering work by Fujino et al. (2012) reported that an equilibrium site

153 distribution of iron may be difficult to achieve, even with annealing by laser heating.

154 However, more recent work showed that the site distribution does not change

155 substantially before and after annealing (Glazyrin et al. 2014; Kupenko et al. 2015; Lin

156 et al. 2016). Also, *in situ* single crystal XRD measurements at high pressure

157 demonstrated that the site occupancy of iron did not change remarkably before, during

158 and after laser heating (Glazyrin et al. 2014). Lin et al. (2016) also showed that the site

159 distribution does not change after annealing, although X-ray emission spectra became

160 sharp after heating. Generally, annealing is important to achieving equilibrium; however

161 at the same time laser heating may cause undesired chemical heterogeneity in the

162 sample (e.g., Sinmyo and Hirose 2010), which can lead to a large uncertainty in

163　property measurements. For more detailed knowledge in the future, it is necessary to

164　develop a heating technique with smaller temperature gradient in the sample, such as

165　externally/internally resistive heating.

166　　　　It is notable that independent studies agree that Fe^{3+} mainly occupies the A-site

167　of Al-free Bdg with moderate Fe^{3+} content (< 0.04 per formula unit) (Lin et al. 2012;

168　Sinmyo et al., 2014b; this study) for samples synthesized at ~25 GPa in a large volume

169　press. Our current results strongly support a small amount of Fe^{3+} distributed onto the

170　B-site of Bdg under pressure. This suggests that A-site of Bdg is more compressible

171　than the B-site, although it should be examined by a future study.

172　**Fe^{3+} in the low-spin state**

173　　　　The new component observed above 36 GPa (Fe^{3+} #2) can be assigned to low

174　spin Fe^{3+} in the B site based on hyperfine parameters reported by Kupenko et al. (2015).

175　Fe^{3+} may have been in the low-spin state when it was distributed onto the B-site of

176　bridgmanite as reported by Kupenko et al. (2015). This inference is consistent with

177　theoretical predictions (e.g., Hsu et al. 2011). Our results show that Fe^{3+} in the low-spin

178　state never exceeds ~18 % of total iron (Fig. 3). This value corresponds to 0.01 cations

179　per formula unit of Fe in the low-spin state in the chemical formula

180　$Mg_{0.971}Fe_{0.064}Si_{0.979}O_3$. Such a minor amount of low-spin iron is consistent with recent

181 experimental studies (Fujino et al. 2012; Lin et al. 2012; Kupenko et al. 2015). It is

182 known that spin crossover can induce pronounced anomalies in the compressibility of

183 minerals (e.g., Fei et al. 2007; Bykova et al. 2016). However, such an anomaly in Bdg

184 compression has hardly been observed, even with single crystal XRD measurements

185 using a soft pressure medium (Boffa Ballaran et al. 2012; Mao et al. 2015). This

186 behavior is possibly due to the limited amount of ferric iron undergoing spin crossover

187 at high pressure. Caracas et al. (2014) showed that spin crossover can be detected by

188 fine analysis of XRD patterns collected for iron-rich $Mg_{0.5}Fe_{0.5}SiO_3$ Bdg. Although

189 Mössbauer spectroscopy is sensitive to the electronic state of iron, a minor amount of

190 Fe^{3+} may not be recognized during analysis of a Fe^{2+}-rich sample. Previous

191 disagreement among studies using XRD, Mössbauer, and X-ray emission spectroscopy

192 (XES) can be explained by the low amount of low-spin Fe^{3+}. Notably, the obtained

193 proportion of low-spin Fe^{3+} is consistent between XES measurements (Fujino et al.

194 2012) and Mössbauer spectroscopy results (Lin et al. 2012; Kupenko et al. 2015; this

195 study) for Bdg synthesized in the multi-anvil press.

196   Figure 4 summarizes the CS and QS values obtained in this study. Fe^{2+} #1 is

197 high spin Fe^{2+} in the A-site (e.g., McCammon et al. 2013). Based on the hyperfine

198 parameters, Fe^{2+} #2 is intermediate spin Fe^{2+} in the A-site (McCammon et al. 2008), or

199   high-spin Fe^{2+} in the A-site with a high QS value (Hsu et al. 2010). CS and QS values of

200   Fe^{3+} #1 are generally similar to Fe^{3+} in the A-site of Al-free Bdg reported at ambient

201   conditions ("M2" and "M3" components in Hummer and Fei 2012). Hyperfine

202   parameters of Fe^{3+} #2 are similar to those for low-spin Fe^{3+} reported in a previous study

203   of Bdg (Kupenko et al. 2015). We note that all of the data by Hummer and Fei (2012)

204   were measured at ambient conditions. It is thus likely that all iron in their study is in the

205   high-spin state, while in our high-pressure study we suggest that the Fe^{3+} #2 component

206   is in the low-spin state. Moreover, the parameters are also quite similar to recently

207   observed values for low-spin Fe^{3+} in Fe_2O_3 at high pressure (Bykova et al. 2016).

208   Theoretical calculations predicted a high QS value (about 2-3 mm/s) for low-spin Fe^{3+}

209   in Bdg (e.g., Hsu et al. 2011). However, our results in relation to Fe^{3+} in Bdg do not

210   show a QS value higher than 1.5 mm/s regardless of the pressure, consistent with results

211   of Lin et al. (2012) and Kupenko et al. (2015). Although the source of this inconsistency

212   is unclear, the results of theoretical calculations may be affected by iron concentration

213   and structural/magnetic configuration (Umemoto et al. 2008).

214   **Implications**

215   Figure 5 summarizes the relation between the concentration of Fe^{3+} and the

216   pressure at which the fraction of low-spin iron is saturated in Bdg. We have fitted the

217   saturation pressure empirically as a function of Fe^{3+} content using an exponential curve.

218   We used data for Bdg synthesized using a large volume press and with known $Fe^{3+}/\Sigma Fe$

219   ratio (Jackson et al. 2005; Li et al. 2006; Fujino et al. 2012; Lin et al. 2012; Kupenko et

220   al. 2015). As the Fe^{3+} content increases, the pressure of saturation increases (Fig. 5).

221   This behavior is similar to the previously reported relation between Fe^{2+} content and

222   spin-crossover pressure in $(Mg,Fe^{2+})O$ ferropericlase (Fei et al. 2007; Yoshino et al.

223   2011). Such a similarity may be due to the general relation between the spin state of

224   iron and the lattice volume altered by the impurity. The amount of Fe^{3+} in the deep

225   Earth depends on the bulk composition of the rock assemblage in the lower mantle,

226   since it is sensitive to Al content and bulk iron content (Nakajima et al. 2012). The

227   concentration of Fe^{3+} in Bdg is reported to be 0.01 - 0.04, 0.04 - 0.06 and 0.15 - 0.30

228   cations pfu in the harzburgite, pyrolite and MORB bulk compositions, respectively

229   (Sinmyo et al. 2011; Nakajima et al. 2012). Spin crossover of Fe^{3+} may take place at a

230   depth of about 900 km (35 GPa) in pyrolite and 1200 km (50 GPa) in MORB

231   composition according to this study (Fig. 5). It should be deeper in the hotter mantle,

232   since the spin crossover occurs at a higher and wider pressure range at high temperature

233   (Wentzcovitch et al. 2009; Wang et al. 2015). Boffa Ballaran et al. (2012) and Mao et al.

234   (2015) suggested that the elastic properties of Bdg are not substantially altered by iron

235   spin crossover. Moreover, as shown in this study, low-spin Fe^{3+} is a minor component

236   throughout the lower mantle; thus the effect on elasticity is not likely to be visible in

237   seismic observations. However, since electrical conductivity is sensitive to the spin state

238   (Ohta et al. 2010; Yoshino et al. 2011), spin crossover may be detected in geomagnetic

239   observations. Additionally, even though the amount of low-spin Fe^{3+} may be small, spin

240   crossover can have a non-negligible effect on the partition coefficient of iron between

241   Bdg and ferropericlase (e.g., Lin et al., 2013), which can strongly influence the structure

242   and dynamics of the lower mantle. The plot shown in Fig. 5 suggests that spin crossover

243   in Fe^{3+} may take place at a depth of about 900 and 1200 km in pyrolite an MORB

244   composition, respectively. Electrical conductivity and the iron partition coefficient

245   could change at such depths due to spin crossover, although available data are currently

246   limited to Fe^{3+}-bearing bulk compositions such as pyrolite (Ohta et al. 2010; Irifune et

247   al. 2010; Sinmyo and Hirose 2013; Prescher et al. 2014). Recent studies have reported

248   that the redox state of the Earth's mantle may be more heterogeneous than previously

249   thought (Frost and McCammon 2008; Stagno et al., 2013; Kaminsky et al., 2015).

250   Nakajima et al. (2012) showed that the Fe^{3+} content is 0.02 per formula unit higher in

251   Bdg synthesized in a rhenium capsule compared to a diamond capsule. This implies that

252   the spin crossover pressure may differ by ~10 GPa between the rhenium-rhenium oxide

253 buffer and the CCO buffer, since the crossover pressure significantly increases with

254 increasing Fe^{3+} content in Bdg (Fig. 5). Redox heterogeneities may be detectable by

255 precise magnetotelluric measurements at lower mantle depths.

470

471   **Figure captions**

472   Figure 1. Selected Mössbauer spectra of Al-free Fe^{3+}-rich Bdg at different pressures and

473   room temperature. Experimental data are indicated by solid circles while the fitted curve

474   is shown by the thick solid line. Components are shaded as indicated in part (c) and the

475   fitting residual is shown beneath each spectrum.

476

477   Figure 2. Pressure dependence of center shift (CS) and quadrupole splitting (QS) for (a)

478   Fe^{2+} and (b) Fe^{3+} in Al-free Bdg. Right and left pointing triangles indicate data taken

479   during compression and decompression, respectively. Our results are largely consistent

480   with previously reported values for Al-free Bdg (Potapkin et al. 2013).

481

482   Figure 3. Relative abundance of components fitted to Mössbauer spectra of Al-free Bdg:

483   (a) Fe^{2+} ; (b) Fe^{3+}. The dashed line shows the initial abundance of Fe^{2+} and Fe^{3+}.

484

485   Figure 4. Variation of CS and QS values for Bdg. Circles, this study; squares, Al-free

486   Bdg at ambient conditions (Hummer and Fei 2012); diamonds, Al-bearing Bdg under 12

487   - 77 GPa (Kupenko et al. 2015). The diameters of the circles are proportional to the

488   pressure at which the values were obtained (i.e., larger diameters correspond to higher

489   pressures).

490

491   Figure 5. Relation between Fe^{3+} concentration (in cations per formula unit) and the

492   saturation pressure of low-spin Fe^{3+} in Bdg (see text for details). The grey line is an

493   empirical fit to the data for Bdg samples synthesized using a large volume press where

494    $Fe^{3+}/\Sigma Fe$ ratios were experimentally determined. Red symbols, Al-free Bdg; blue

495   symbols, Al-bearing Bdg. Filled symbols indicate the data used for fitting (Color

496   online). "Harzburgite", "Pyrolite" and "MORB" denote possible concentrations of Fe^{3+}

497   in Bdg in harzburgitic, pyrolitic and basaltic rock, respectively (see text for details).
