22 **Abstract**

23 Electron backscatter diffraction data (EBSD) yield plentiful information on microstructure and

24 texture of natural as well as experimentally produced mineral and rock samples. For

25 instance, the characterization of microstructures and textures by EBSD allows for the

26 evaluation of phase equilibria. Furthermore, determination of the preferred orientations of

27 crystals using EBSD yields constraints on deformation mechanisms and history of the

28 minerals/rocks. The latter affects bulk rock properties such electrical conductivity and

29 seismic anisotropy. EBSD is also applied to advance our understanding of various phenomena

30 such as seismic wave attenuation in the Earth deep interior that might be caused by the

31 presence of interfacial small degrees of melt fractions, or free fluid phases.

32 In standard EBSD software solutions, the original EBSD patterns are rarely saved and indexing

33 routines result in many artifacts, such as pseudo-symmetry or unindexed pixels at interfaces

34 that may be misinterpreted as amorphous material, such as a melt.

35 Here we report the first application of an extension of the dictionary indexing (DI) approach

36 proposed by Chen et al. (2015), an alternative indexing routine, to multiphase geologic

37 materials. The DI method is independent of the EBSD system, and thus of the used

38 detector/software. The DI routine generates simulated EBSD patterns for all possible crystal

39 orientations, taking the sample composition and experimental setups into account. The

40 resulting pattern database is called a dictionary. The experimental Electron Backscattering

41 Pattern (EBSP) images are indexed by comparing them to the dictionary using a dot-product

42 algorithm. We evaluate the new DI method in comparison to standard routines and highlight

43 advantages and disadvantages.

44   To test and compare the DI's reliability and performance, we apply the routine to two

45   scientifically challenging samples: (1) A nominally anhydrous ('dry') residual eclogite

46   composed of garnet (cubic), clinopyroxene (monoclinic) and an amorphous melt, where the

47   different degrees of hardness of the phases cause surface topology; and (2) a pure forsterite

48   (olivine) polycrystalline sample produced by vacuum sintering (Koizumi et al. 2010). The

49   acquired EBSD patterns are of low quality for the latter as a result of fast data acquisition to

50   reduce the on-line machine time.

51   We conclude that the new DI method is highly precise and surpasses the performance of

52   previously available methods while being computer time and -memory consuming. We find

53   that the DI method is free of pseudo-symmetry-related problems. Interpolation of data

54   becomes obsolete and high reproducibility is obtained, which minimizes the user impact on

55   the final dataset. The latter is often caused by applying several cleaning steps on EBSD maps

56   with low indexing fraction. Finally, much higher scientific integrity is ensured by the image

57   collections as described above, which requires that all patterns are saved. This in turn allows

58   later re-analyses if required. The DI routine will help to achieve more reliable information on

59   interface properties of geological samples, including amorphous materials, and to improve

60   the accuracy of large-scale Earth mantle process models.

63   EBSD - electron backscatter diffraction, DI - dictionary indexing, EBSD simulation, melt

64   distribution, wetting angles, GBCD - grain boundary character distribution, grain boundary,

65   dunite, olivine, eclogite, Earth's mantle processes

66   **Introduction**

67   Electron backscatter diffraction (EBSD) is a key technique to characterize polycrystalline

68   samples especially when focusing on crystal fabrics (e.g. crystal preferred orientation, CPO;

69   shape preferred orientation, SPO), defect structures such as interfaces, phase-, grain-, and

70   twin boundaries, as well as the distribution of impurities or melt on interfaces (e.g. Faul and

71   Scott 2006; Le Roux et al. 2008; Manthilake et al. 2013; Soustelle et al. 2014).

72   Manual EBSD techniques have been developed in 1970's, where electron backscatter pattern

73   (EBSP) were collected on electron-sensitive photographic plates (Venables and Harland

74   1973). Interactive indexing was developed by David Dingley in the late 1980's (e.g. Dingley

75   and Baba-Kishi 1986). Automated EBSD was considerably advanced in the early '90s by Brent

76   Adams and Stuart Wright (Adams et al. 1993) but the first Kikuchi images date back to

77   Kikuchi (Kikuchi 1928). Quantitative texture analysis is routinely performed with millimeter to

78   tens of nanometer spatial resolution. Collected orientation data are used to obtain grain size

79   distributions (Adams et al. 1993), phase fractions, dislocation densities and surface

80   information (Wright and Nowell 2006). Furthermore, the application of EBSD allows for the

81   investigation of deformation mechanisms (e.g. Wheeler et al. 2001; Michibayashi and

82   Mainprice 2004; Warren and Hirth 2006; Prior et al. 2011; Michibayashi et al. 2016) and the

83   identification of new phases (Bandli and Gunter 2012). EBSD has developed into a standard

84   tool for the characterization of fabrics in rocks and materials (e.g. Prior et al. 1999; Schwartz,

85   A.J., Kumar, M., Adams, B.L., Field 2009; Morales et al. 2011). Its application also allows for

86   the derivation of the orientation distribution function (Bunge and Esling 1982), for which

87   10,000 grains already provide statistically robust information (Maitland and Sitzman 2007;

4

88   Wright et al. 2007), while others trust calculate fabric strength from a total number of

89   crystals of only 100 to 150 (e.g. Ismaïl and Mainprice 1998). Many of these types of

90   information can be retrieved from EBSD orientation data using freely available softwares,

91   such as MTEX (Bachmann et al. 2010). MTEX permits highly flexible data processing, scripting

92   for batch processing of large data sets and precisely reproducible data treatment. Likewise,

93   more sophisticated information, such as internal grain deformation and strain measurements

94   using high (angular) resolution EBSD (HR EBSD) (Crawford and Was 1991; Wilkinson et al.

95   2006; Ram et al. 2016) can be gained. Calculating the geometrically necessary dislocation

96   density has had great impact on deformation quantification in recent years (Cordier et al.

97   2014). Moreover, grain boundaries are considered a neglected key for deformation in

98   general (Lloyd et al. 1997; Sun et al. 2016). More recently, EBSD has evolved into a robust

99   method that allows for the study of the characteristics of interfaces by enabling the

100   acquisition of maps with high spatial resolution over large areas, including grain boundaries

101   (Saylor et al. 2004b; Dillon and Rohrer 2009; Rohrer 2011; Kelly et al. 2016). Such methodical

102   advances overcome the lack of statistical accuracy (Lloyed et al., 1997).

103   AltHough-EBSD hardware has evolved quickly, software solutions have remained Hough-

104   transform based (i.e. a routine that allows to identify Kikuchi bands from electron

105   backscatter pattern by orientation and intensity), and have not advanced to meet the

106   requirements for the study of interface properties. In standard software solutions, collected

107   Electron Backscattering Patterns (EBSP) are directly processed and typically only the

108   extracted orientation data are permanently saved, while the original data (the EBSPs) are

109   discarded. We like the reader to note that both Oxford and EDAX systems allow for saving

5

110   the EBSPs for example in multiple image formats (jpg, bmp, tiff, etc.). Recently, binary

111   compressed formats (pat and hdf5) have become available. This allows for re-processing of

112   the data using commercial software packages (Wright et al. 2015), but also facilitates a more

113   extensive use of the dictionary indexing (DI) routines (Chen et al. 2015). EBSD users should

114   benefit from these developments, because if the indexing procedure is later found to be

115   wrong or of poor quality, the data can be re-interpreted in contrast to former times (Pinard

116   et al. 2011).

117   A pixel is also discarded if no indexing solution for the pattern is found by the standard

118   software, even if Kikuchi bands were present in the EBSP. Generally, data processing is still

119   far from optimal, which limits the power of EBSD (Tao and Eades 2005). Furthermore,

120   indexing results and quality vary strongly with the operator's experience, sample surface

121   preparation as well as software settings that are often difficult to access within the various

122   software packages available. For example, the settings of the Hough-transform will strongly

123   influence which bands can be detected in an experimental Kikuchi pattern; these settings

124   include Hough-space resolution, Butterfly-masks, size, minimum peak intensity, minimum

125   distance between peaks, peak symmetry and binned pattern sizes. The indexing result also

126   depends on how many bands are chosen to be included in the indexing routine. However,

127   the optimal value depends, in turn, on the software used in the routine. Different strategies

128   include the use of band orientation, width and intensity. The latter is applied only for the

129   selection of the extent of the use of the hkl's in the database required for indexing. Thus, the

130   information encoded in relative band intensities is discarded (Nolze and Winkelmann 2016).

131   The power of full data acquisition, storage, and the superiority of post-processing for noisy

6

132   EBSD patterns, scanning electron microscope (SEM) images and chemical information (Tao

133   and Eades 2005; Payton and Nolze 2013; Wright et al. 2015a,b), as well as the superior

134   accuracy of the DI approach (Ram et al. n.d.) have previously been emphasized.

135   In this study, we propose an extension of an alternative indexing routine, the DI approach

136   (e.g. Chen et al. 2015), and evaluate the applicability of the method to overcome long-

137   standing difficulties and uncertainties using EBSD on material interface properties related

138   problematics. The here-presented results are obtained from data sets where all EBSPs are

139   saved. We analyzed two challenging samples to test the new DI routine. The first sample, a

140   nominally 'dry' residual eclogite Res2_16 (Rosenthal et al., 2014) contains a melt phase that

141   cannot by indexed by standard EBSD software's. Res2_16 also contains clinopyroxene, a

142   mineral with monoclinic crystal structure, as well as garnet (cubic). The second sample is an

143   uncoated nominally 'dry' forsterite (Mg_2SiO_4) polycrystalline sample with a small average

144   grain size of about 6 μm. In the latter olivine sample, surface charging effects and applied

145   fast acquisition conditions to reduce the on-line machine time result in low pattern quality.

146   For data processing, either the Ametek® EDAX TSL OIM™ Analyses (7) EBSD-software

147   (hereafter: OIM) or the Oxford instruments HKL CHANNEL5 software (hereafter HKL) were

148   employed and compared to the DI approach applied to the same data sets. In both software

149   packages, OIM and HKL, all individual EBSD patterns are Hough-transformed. The Hough-

150   transform replots every pixel of an EBSP by the distance and angle of a vector pointing to this

151   pixel. High intensity peaks are subsequently indexed, using a database calculated from the

152   crystal structure and lattice parameters where the fitting includes angles between bands,

153   which are the angles between lattices planes. For a set of three bands and angles a crystal

154   orientation can be determined; often several such triplets are used to obtain a more

155   unambiguous indexing.

156   In contrast, to obtain the standard Euler angle information using the DI method, all

157   experimental EBSPs are compared with a database (dictionary) of simulated EBSPs until a

158   best match is obtained. The EBSPs are simulated using a physics-based forward model

159   (Callahan and De Graef 2013) combined with a uniform sampling of orientation space (Roşca

160   and De Graef 2013; Singh and De Graef 2016). The procedure is explained in detail below.

161

162   **Samples and Methods**

163   The methods part is divided into three sections. First we introduce the two samples

164   investigated. Then we summarize the specific settings used for EBSP acquisition and indexing

165   using OIM and HKL systems, respectively. Finally, we outline the dictionary indexing (DI)

166   approach.

167   **Sample Materials**

168   **Sample 1.** The 'dry' (nominally anhydrous) residual bimineralic eclogite, containing sub-

169   /euhedral crystals of garnet up to 70 μm, tabular crystals of clinopyroxene up to ~30-40 μm,

170   and a melt fraction (Res2_16; Rosenthal et al. 2014).

171   This sample represents a residue, which suffered melt extraction of a 'dry' residual coesite-

172   bearing eclogite at 3 GPa and 1350°C on adiabatic ascent.

173   Garnet in our sample is a solid solution of mainly pyrope ($Mg_3Al_2Si_3O_{12}$; 52.6 mol.%),

174   almandine ($Fe_3Al_2Si_3O_{12}$; 29.6 mol.%), and grossular ($Ca_3Al_2Si_3O_{12}$; 17.8 mol.%) and contains

175   minor TiO_2 (0.56 wt.%) and Na_2O (0.20 wt.%). Clinopyroxene is a solid solution of jadeite

8

176   (NaAlSi$_2$O$_6$; 22.6 mol.%), diopside-hedenbergite (CaMgSi$_2$O$_6$-CaFeSi$_2$O$_6$; 33.0 mol.%),

177   enstatite-ferrosilite (MgMgSi$_2$O$_6$-FeFeSi$_2$O$_6$; 21.8 mol.%), Ca-tschermaks (CaAlAlSiO$_6$; 13.8

178   mol.%), Ca-eskolaite (Ca$_{0.5}$AlSi$_2$O$_6$; 5.5 mol.%), and Al-buffonite (CaMg$_{0.5}$Ti$_{0.5}$AlSiO$_6$; 3.3

179   mol.%). The quenched liquid (melt) is of basaltic-andesitic composition.

180   The experiment ran in an end-loaded Boyd-England half-inch (1.27 cm) piston-cylinder

181   apparatus at the Research School of Earth Sciences (RSES), Australian National University

182   (ANU) for 146 hours. Experimental and analytical procedures are outlined in Rosenthal et al.

183   (2014).

184   **Sample 2.** The forsterite sample was prepared using the vacuum sintering method of Koizumi

185   et al. (2010). The polycrystalline sample was synthesized from mineral powders with particle

186   sizes of < 100 nm. The source powders of high purity colloidal SiO$_2$ and Mg(OH)$_2$ were mixed

187   in a ball mill in highly pure ethanol solvent for about a day. This is followed by a calcination

188   step in an alumina tube furnace at 960°C under the flow of oxygen to remove the

189   decomposition products of H$_2$O and CO$_2$ efficiently. One of the most important points to

190   obtain these highly dense compacts is to use fully reacted nm-particle as reaction are

191   associated with volume changes that can disturb the densification. The calcined powders

192   were compacted to the desired shape and pressed at 200 MPa for 10 minutes. Sintering was

193   performed at vacuum of about 1* 10-3 Pa at temperature of 1380°C for 10 min. The final

194   dense polycrystalline sample contains less than 2 vol% of enstatite to buffer the silica

195   activity. The average grain size is about 6 μm.

196   **EBPS acquisition and standard analysis using commercial EBSD software packages**

197   **EBSD of Sample 1.** The EBSD patterns of the garnet-clinopyroxene-melt sample were

9

198   acquired using a Zeiss Leo Gemini 1530 Schottky FE-SEM operated at an accelerating voltage

199   of 20 keV and a probe current of about 2.0 -2.5 nA (60 mm aperture and high current

200   option).

201   The specimen was placed at 15.2 mm working distance, which corresponds to a sample-

202   scintillator distance fitted by the DI algorithm of 14.828 mm. The scans were run at

203   0.3µm*0.3µm step size. The microscope is equipped with a NordlysS camera from Oxford

204   Instruments with a CCD resolution of 1344*1024*12bit. Acquisition was set to 0.152 seconds

205   per pattern and good pattern quality was obtained, while having a carbon coating of 4nm

206   thickness. Patterns were captured with 4*4 binning on the camera, with window averaging of

207   8, an averaged background for background subtraction, maximum camera gain, and no

208   image processing besides automated contrast enhancement (details are given in Oxford

209   Channel 5 User Manual). After binning, the pattern was further compressed by 50% into

210   "*.jpg" format. These further compressed images were analyzed using the DI routine.

211   Automated indexing routine and analyses were performed using HKL.

212   Garnet was indexed using the cubic symmetry Ia3d and lattice parameters of a=11.459 Å,

213   which may vary up to 11.87 Å related to substitution. Clinopyroxene was indexed using the

214   crystal parameters of diopside ($CaMgSi_2O_6$) in the monoclinic symmetry and lattice

215   parameters included in the HKL database, $a = 9.746\ \dot{A}, b = 8.990\ \dot{A},\ c = 5.251\dot{A}$ and

216     $\alpha = 90°, \beta = 105.629°,\ \gamma = 90°$. For the automated SEM-EBSD measurements, the

217   reliability of the indexing procedure is critical (Prior et al. 1999). The reference file consisted

218   of the 8 strongest reflections for garnet, the 15 strongest reflections for clinopyroxene and

219   no reference for the melt phase. The reflections were calculated from the scattering factors

220   of the atoms using the kinematical diffraction theory. Even tHough-multiple scattering occurs

221   in the interaction volume of the electron beam with the bulk sample (dynamic diffraction),

222   the kinematical intensities of the reflections are approximately correct. In more than 56% of

223   the data points a good solution was found, the other 44% were not indexed. The criteria for

224   rejection of a solution were (1) if less than 5 reflection bands could be identified, where

225   three non-coaxial bands are considered sufficient to yield a unique solution; (2) if the mean

226   angular deviation of the calculated reflection bands in Hough-space was larger than 1.3°. One

227   source of problems arising from the indexing algorithm is a low indexing success rate across

228   boundaries. This is caused by the overlapping diffraction patterns from two crystals at grain

229   boundaries and results in a low confidence index and ultimately no solution. To obtain maps

230   with 100% indexed data points, post processing would be required to assign grain boundary

231   data points to orientations that are identical to the orientations of the majority of its eight

232   neighbors, and thus one or the other grain. However, such cleaning of data is not

233   recommended in the presence of a melt phase, as the system has no way to distinguish

234   between different types of unindexed patterns. Thus, no post processing was performed.

235   Nevertheless, it might be possible to discriminate the phases based on the Band Contrast

236   map, where band contrast is lower in an amorphous region; band-free patterns can be

237   compared to a pattern resulting from the overlap of two (band-rich) patterns.

238   **EBSD of sample 2.** The EBSD patterns of the forsterite sample were acquired on a FEI Quanta

239   SEM at Carnegie Mellon University (Pittsburgh, PA, USA) using a probe current of 2 nA, 30 kV

240   acceleration voltage, and a step size of 0.2μm*0.2 μm. The microscope is equipped with a

241   DigiView 5 camera with 1395*1040*12 bit resolution and the EDAX/TSL OIM DC software

11

242   (version 7.0; EDAX/ TSL, Draper, UT, USA). Patterns were captured with 4*4 binning on the

243   camera. A maximum camera gain, background removal but no image processing were

244   applied. The recorded patterns have a dimensionality of 61*61 pixels in .jpg format.

245   For enstatite we used orthorhombic symmetry Pbca and lattice parameters of

246    $a = 18.241 \, \dot{A}, b = 8.83 \dot{A} \, c = 5.185 \, \dot{A}$. For forsterite, we assumed orthorhombic symmetry

247   Pbnm with the lattice parameters $a = 4.761 \, \dot{A}, b = 10.225 \, \dot{A} \, c = 5.994 \, \dot{A}$.

248   The general parameters were set to a binned pattern size of 120 pixels with a theta step size

249   of 1°, i.e. a Rho fraction of 80%. The Max Peak Count was set to 11, the minimum to 5. These

250   parameters were kept constant for all indexing runs.

251   To obtain crystal orientation maps, data were processed using OIM. First, the Kikuchi bands

252   utilized for orientation derivation were detected using the classical two-dimensional Hough-

253   transform-based algorithm. They were applied to images, which were subject to the

254   following image processing: background subtraction, median smoothing, dynamic

255   background division, and normalization of intensity histogram. We used a classic Hough-

256   convolution mask of 9*9. The minimum and maximum Hough-peak magnitudes were set to 5

257   and 19 respectively. Peak symmetry was set to 0.6, and 7 bands were chosen to index

258   forsterite, 25 for enstatite.

259

260   **Dictionary indexing (DI) approach**

261   The DI approach uses a set of pre-computed EBSD patterns (EBSPs), known as "the

262   dictionary," to find a best matching pattern for each experimental EBSP (Park et al. 2013;

263   Chen et al. 2015). A schematic working procedure of the dictionary indexing process is

12

264   illustrated in figure 1. To obtain simulated EBSPs as similar to the experimental EBSPs as

265   possible, a physics-based Generalized Forward Projector (GFP) (Callahan and De Graef 2013)

266   of the EBSD signal is employed. This EBSP generation process is combined with a geometrical

267   model of the detector system (including the pattern center coordinates, the detector pixel

268   size, and the distance between detector and sample), and a uniform sampling of the

269   orientation space *SO(3)*; the resulting electron backscatter diffraction pattern is called the

270   master pattern, depicted in figure 2. This master pattern can be thought of as the back-

271   scattered electron (BSE) yield on a spherical surface for a hypothetical spherical sample with

272   an electron source at its center. *SO(3)* is the set of special orthonormal 3x3 matrices that

273   represent 3D orientations. The sampling approach is based on an equal-volume mapping

274   between a cubical grid, the "cubochoric space," and the northern hemisphere of unit

275   quaternions, which is isomorphic with *SO(3)*. The approach thus creates a uniform sample of

276   orientations that provide the pattern labels in the dictionary (Roşca et al. 2014). The spacing

277   of the sampling grid corresponds to an average angular step size; selecting a finer grid

278   reduces the angular step size in orientation space. The details of the sampling approach, as

279   well as applications to constant misorientation sampling, are described elsewhere (Singh and

280   De Graef 2016). The uniform orientation sample is obtained by creating a uniform cubical

281   grid, mapping all the grid points into Rodrigues space (Morawiec and Field 1996; Morawiec

282   2010; Roşca et al. 2014), and keeping only those points that fall inside the fundamental zone

283   (FZ) for the relevant crystal symmetry (one of the 3D rotational point groups).

284   For cubic symmetry (rotational point group **432**) and *N=100* sampling points (an average

285   angular step size of *1.4°*) along the cubochoric semi-edge, a total of $N_d=333,227$ unique

13

286   sampling points are found (e.g for garnet). For the monoclinic rotational point group **2**

287   instead, the number of unique sampling points (orientations) at the same angular step size

288   increases to N_d=*4,000,424,* (e.g. for clinopyroxene). Similar considerations yield 2,000,037

289   sampling points for forsterite and enstatite.

290   The required input parameters for the creation of a pattern dictionary are: (1) the crystal

291   structure; (2) the microscope acceleration voltage and the sample tilt angle; (3) the detector

292   geometry parameters, including the detector tilt angle, the pattern center coordinates, and

293   the distance between the illuminated region on the sample and the scintillator screen; and

294   (4) a uniform orientation sampling grid with a step size of about *1.4°* (i.e., *N=100*). Of these

295   input parameters only (1) is a true operator choice, the remainders are fixed as instrument

296   parameters or extracted in a fitting routine from one EBSP of the map center (Singh et al.

297   n.d.).

298   The dictionary patterns are then computed for the pattern size and geometric conditions

299   appropriate to the experimental EBSPs. In this study, we use the dot product between

300   patterns as the similarity metric. Because of the large number of dictionary patterns needed

301   for lower symmetry crystal structures (i.e., orthorhombic, monoclinic, and triclinic), it was

302   found to be more efficient to compute these dictionary patterns in real time during the

303   indexing run instead of pre-computing them and storing them on disk.

304   The master patterns for the crystal structures used in this study are shown in figure 2. On the

305   top row of figure 2, the master patterns for forsterite, garnet and enstatite are shown as

306   stereographic projections. In all projections, the crystallographic a-axis points horizontally

307   towards the right, and the reciprocal c*-axis is normal to the plane of the projection. In the

14

308   bottom row of figure 2, two projections are shown for clinopyroxene: the northern

309   hemisphere projection on the left and the southern hemisphere on the right. These master

310   patterns are sampled using bi-linear interpolation during the computation of the dictionary

311   EBSD patterns.

312   Pattern matching is carried out using a dot-product approach. As an example, consider the

313   dot-product between two 4-D vectors with components *v = (23,18,5,31)* and *w =*

314   *(24,16,6,30):* the dot-product can be defined as:

315    $\boldsymbol{v}.\boldsymbol{w} = |\boldsymbol{v}||\boldsymbol{w}| \cos(\theta_{vw}),$

316   where vertical bars indicate the vector norm, and θ_{vw} is the angle between the two vectors.

317   This relation can be rewritten by introducing normalized vectors,

318    $\cos(\theta_{vw}) = \hat{\boldsymbol{v}}.\hat{\boldsymbol{w}},$

319   where the hat indicates a unit length vector. With $\hat{\boldsymbol{v}}$ = (0.5363,0.4197,0.1166,0.7223) and $\hat{\boldsymbol{w}}$

320   = (0.5708,0.3805,0.1427,0.7135), we obtain $\hat{\boldsymbol{v}}.\hat{\boldsymbol{w}}$ =0.9983, so that θ_{vw} = 3.38°. Using a third

321   vector **u** = (18,21,11,25), it is easy to show that θ_{vu} = 13.34° and θ_{wu} = 14.27°. From the

322   magnitude of the angle we can see that the vectors **v** and **w** are similar, whereas the pairs **v-**

323   **u** and **w-u** are dissimilar, assuming we define similarity in terms of an angular threshold of 5°.

324   If we instead employed a threshold of 15°, all three vectors would be considered to be

325   similar. In the DI approach, the same type of analysis is applied to the experimental and

326   simulated EBSPs. The angular threshold of the DI routine is the same as the angular

327   resolution of the simulations. Each EBSP, with number of pixels in x and y direction N_x by N_y,

328   is reorganized as a column vector of $N_x N_y$ elements containing the grayscale values of the

329   EBSP and normalized to unit length. This reformatting is performed for all N_e experimental

15

330   patterns and N_d dictionary patterns. Representing the experimental patterns by the vectors

331     $\widehat{v}_j$ with $1 \leq j \leq N_e$ and the dictionary patterns by $\widehat{w}_k$ with $1 \leq k \leq N_d$, the dictionary

332   indexing approach then involves the computation of all dot products $\widehat{v}_j . \widehat{w}_k$ and, for each j,

333   ranking of the N_d products from largest to smallest. For a given experimental pattern j, the k-

334   value for which the dot-product is largest (i.e., the smallest angle between the two vectors)

335   represents the dictionary pattern that is most similar to this experimental pattern j. Since

336   each dictionary pattern corresponds to an orientation from the uniform sample of

337   orientations, determination of the highest dot-product (or the smallest angle θ_{jk}) for a given

338   j is equivalent to indexing the experimental pattern j. The fit quality (CI in OIM), in terms of

339   the **highest dot product value** drops after the best match and decreases drastically when a

340   mismatch of more than few degree is reached. These disorientations obtained from different

341   dot-product fits are evaluated in figure 3. We match one experimental EBSP with all

342   simulated EBSPs and plot them ordered according to decreasing dot-product. The best match

343   has the minimal disorientation that is maximally the resolution of the simulated dictionary,

344   then the second best match is plotted and the disorientation between simulated pattern one

345   and two is the disorientation displayed on the abscissa. Furthermore the average dot product

346   values are displayed directly as a 2D map in figure 4a, and figure 5f.

347   The indexing accuracy in commercial OIM systems is described using the confidence index

348   (CI), which is defined in terms of the number of Kikuchi bands that can be reproduced by

349   different matching solutions. In the OIM analysis software, for example, one orientation

350   solution is derived from three intersecting Kikuchi bands. Typically more than three bands

351   are found and all possible combinations of band triplets receive a vote. The orientation with

352   the most votes is chosen as the solution. The CI is then defined as the difference in votes

353   received by the highest and second highest-ranking solutions (*V1* and *V2* respectively)

354   divided by the number of total possible votes, V_{ideal}:

$$CI = \frac{(V_1 - V_2)}{V_{ideal}}$$

355   Low CI data are typical for very poor pattern quality, e.g. containing many scratches or grain

356   boundaries where patterns of two adjacent grains overlap. Also, a value of CI = 0 does not

357   necessarily indicate incorrect indexing (technical note from EBSD). Finally, contrary to the

358   highest dot product value in the DI approach, the CI is not an absolute measure as it depends

359   on how many bands were chosen by the operator to be included in the indexing routine.

360   In HKL, the mean angular deviation (MAD) is used to express the reliability of indexing, where

361   an average angular misfit between the detected and indexed Kikuchi bands is given. The

362   highest dot product value of the DI approach is thus more similar to MAD then to CI.

363   It should be noted that in the DI approach there is no analysis of any of the features present

364   in the EBSPs, such as the background intensity profile and the Kikuchi bands. In contrast to

365   the more commonly used Hough-space analysis, the DI routine weights all pattern pixels

366   equally and no portion of the pattern is discarded. In the bottom row of figure 4e we display

367   representative experimental electron backscatter patterns chosen arbitrarily from the set of

368   saved patterns.

369   In some cases, it is found to be useful to process the EBSD patterns to enhance contrast. Any

370   processing steps were performed on both the experimental patterns and the simulated

371   dictionary patterns to avoid the introduction of artifacts in one set that would complicate the

372   matching process. The processing carried out on all of the patterns used for this paper

17

373   consists of a single step using an adaptive histogram equalization (AHE) filter (Pizer 1987),

374   which spreads the intensities in the pattern histogram to cover the available range of [0,255]

375   more evenly. As a result, the pattern contrast is significantly enhanced, as apparent when

376   comparing the patterns inserted in figure 4b. The red curve represents the frequency of

377   specific gray values before applying the AHE filter; the blue curve shows the filtered data. The

378   AHE filter is then followed by pattern normalization to generate vectors of unit length, which

379   are subsequently used in the dot-product computation.

380   In addition to the dot-product computations between experimental and simulated patterns

381   (referred to as "pattern indexing" hereafter), there are several other dot-product based

382   operations that can provide valuable information about the sample as well as the quality of

383   the indexing results. We will describe some of them in the following and compare the

384   derived information with similar information provided by standard software solutions.

385   Examples of each of these maps will be presented below (see "Results").

386   **Average Dot Product (ADP) Map.** Consider an experimental region of interest (ROI) with M_x

387   by M_y sampling points and a sampling step size D; we will label a sampling point by its row

388   and column indices, r and c, respectively, in the ROI. After application of the AHE filter and

389   pattern normalization, one can generate an average dot-product (ADP) map by computing

390   the average dot-product value, $\alpha_{r,c}$, for each pattern with its four nearest neighbor patterns

391   as follows:

392     $$\alpha_{r,c} = \frac{1}{4}(\widehat{\boldsymbol{v}}_{r,c}.\widehat{\boldsymbol{v}}_{r+1,c} + \widehat{\boldsymbol{v}}_{r,c}.\widehat{\boldsymbol{v}}_{r-1,c} + \widehat{\boldsymbol{v}}_{r,c}.\widehat{\boldsymbol{v}}_{r,c+1} + \widehat{\boldsymbol{v}}_{r,c}.\widehat{\boldsymbol{v}}_{r,c-1}).$$

393   For patterns at the ROI edges and corners, the number of contributing dot products will be

394   equal to 3 and 2, respectively. A 2-D map of the $a_{r,c}$ values then displays how similar each

18

395   sampled pixel location is to its nearest neighbors. For pixels on or near a grain or phase

396   boundary, for instance, the average dot-product will in general be lower than for pixels inside

397   a grain. This results from the fact that the orientation of neighboring grains is different,

398   which leads to changes in the EBSP upon crossing the boundary (figure 4b, c, d, figure 5h,

399   figure 6d, figure 7d). The ADP is therefore related to indexing quality and can be calculated

400   for every pixel from the stored EBSPs. A measure similar to the average dot product in

401   conventional Hough-based indexing is the kernel average misorientation map (KAM), where

402   each pixel has a value equal to the average disorientation of this pixel with respect to its

403   neighbors. The ADP-map is compared to the KAM-map in figure 5 b, e, h. This will highlight

404   grain and phase boundaries, i.e. similar to KAM maps obtained in OIM analyses. However,

405   grain boundaries appear black in the ADP map which highlights similarity, and white in the

406   map KAM which highlights dissimilar orientations (figure 5 b,e,h).

407   **Orientation Similarity Map.** Since the DI approach returns a ranked list of dot products

408   between an individual experimental pattern and all of the dictionary patterns, one can store

409   not only the best match (highest dot-product) value, as in the highest DP-map (figure 5f), but

410   also a series of near-matches. For each sampling point, we consider the list of M near-

411   matches (M is typically 20 or 30), and compare this list to the corresponding lists of the four

412   nearest neighbors of the sampling point. If we write the ordered list of near-matches for a

413   given point (r,c) as a set $S_{r,c}$, then we can define the near-match similarity index, $\eta_{r,c}$, as the

414   average value of the cardinalities (#) of the intersections with the neighboring sets:

$$\eta_{r,c} = \frac{1}{4}\big(\#(S_{r,c} \cap S_{r-1,c}) + \#(S_{r,c} \cap S_{r+1,c}) + \#(S_{r,c} \cap S_{r,c-1}) + \#(S_{r,c} \cap S_{r,c+1})\big).$$

415   Plotting this index as a function of the sampling point location then results in the orientation

19

416   similarity (OS) map, as displayed in figure 5g and 5i, where it compares to the CI map

417   displayed in figure 5c. Near a grain or phase boundary, neighboring sets will be more

418   different than in the grain interior, so that the OS map shows grain and phase boundaries

419   too.

420

421   **The Image Quality (IQ) parameter** used in standard software solutions essentially refers to

422   how easily the Kikuchi bands can be detected by the Hough-transform approach.

423   In the OIM software package, IQ is defined as the average height of the detected peaks in the

424   Hough-transforms multiplied by 5, this is plotted in figure 5a. The quality of diffraction

425   patterns is dependent on the strain in the diffraction volume of material, the phase of the

426   material, the presence of impurities, camera parameters, vacuum, and coating conditions

427   among other factors. Thus IQ is not an absolute measure of the quality of a pattern (adapted

428   from the EDAX manual of OIM TSL version 7.2).

429   Since the DI approach does not focus on detecting individual bands, an alternative definition

430   of the image (or pattern) quality is needed. In the present work, we chose to employ the

431   *"pattern sharpness" Q parameter* defined by Lassen (Krieger Lassen et al. 1994). The pattern

432   sharpness is given by:

433     $Q = 1 - \dfrac{J}{J_{res}w_{tot}},$

434   where

$$J = \sum_{h=-\frac{N}{2}}^{\frac{N}{2}} \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} w(h,k)|\boldsymbol{q}|^2;$$

$$J_{res} = \frac{1}{N^2} \sum_{h=-\frac{N}{2}}^{\frac{N}{2}} \sum_{k=-\frac{N}{2}}^{\frac{N}{2}} |\boldsymbol{q}|^2;$$

$$w_{tot} = \sum_{h=-N/2}^{N/2} \sum_{k=-N/2}^{N/2} w(h,k).$$

435   The function *w(h,k)* is the power spectrum of the experimental EBSD pattern, and the vectors

436   **q** are the frequency vectors with components *(h,k)*. The sharper the Kikuchi bands, the higher

437   the high-frequency content of the power spectrum and, therefore, the closer Q will be to

438   unity. The sharpness parameter makes it possible to compare EBSD patterns from different

439   grains or phases on a uniform scale that does not depend on the number of Kikuchi bands in

440   the pattern. An example Q map for forsterite is displayed in figure 5d; the values range from

441   0.40 (black) to 0.48 (white).

442   Note that the only operator choice using the DI method is the choice of used phases, which

443   also includes the atom positions of the asymmetric unit and the crystal class. Using a

444   representative EBSP the imaging parameters are refined. The latter yield the pattern center

445   coordinates and the sample-scintillator distance. The resulting pattern orientations can then

446   be analyzed using the conventional techniques in commercial software such as OIM or HKL;

447   or using the freely available matlab tool box MTex (Bachmann et al. 2010).

448

449   **Results**

450   **Sample 1.** Figure 3 displays the average dot product for the top fifty matches for each

451   sampling point of the partially molten residual eclogite averaged over the complete data set

21

452   as a function of the disorientation angle between the top match and the lower matches for

453   both the garnet (red) and clinopyroxene (blue) phases. The orientation for which the highest

454   dot product occurs is used as the orientation assigned to the experimental pattern. The next

455   nearest matches all have lower dot products and correspond to a gradually increasing

456   disorientation with respect to the best match pattern. For disorientations larger than about

457   10°, the dot product values level out and oscillate around a background value.

458   The histograms in Figure 4b correspond to the raw EBSD pattern (top inset and nearly

459   Gaussian curve), and the EBSD pattern after adaptive histogram equalization (bottom inset

460   and nearly flat curve). The equalization filter enhances the contrast in the patterns, and is

461   applied to both experimental and dictionary patterns before computation of the dot

462   products. Figure 4a & c illustrate the average dot product (ADP) map before and after

463   equalization. Individual grains in Figure 4a indicate contrast differences as a result of electron

464   channeling in different crystal orientations. The brightest regions correspond to the melt

465   phase. In figure 4c instead, the main contrast differences are produced by the different

466   phases. That is, the order of decreasing 'brightness' in Fig. 4c is clinopyroxene > garnet >

467   melt. In Figure 4d an area of a garnet grain next to a melt pool is encircled. The slight

468   variations in the gray level are caused by the amorphous melt pattern superimposing a

469   weaker pattern of a garnet. This visualizes the third dimension captured by the interaction

470   volume of the electron beam within the sample interior.

471   A raw EBSD phase map collected using the HKL system is displayed in figure 6a. In the

472   presence of melt at the interfaces, data cleanup is not recommended. Figure 6e shows the

473   phase map derived using the four individual highest dot product maps displayed in figure 6

22

474   f,g,h,i for clinopyroxene, garnet, melt pools and garnet-clinopyroxene phase boundaries,

475   respectively. The joint histogram in figure 6b shows the dot product values for the best fit for

476   clinopyroxene and garnet; there are 250,000 points in this scatter plot. The two dominant

477   clusters correspond to high dot products obtained using the garnet dictionary and the

478   clinopyroxene dictionary, the smaller cluster to the lower left corresponds to EBSD patterns

479   that have a poor match against both dictionaries; those points are assigned to the melt

480   phase. Points above the diagonal of the joint histogram have a larger best match with

481   respect to garnet and are hence assigned to the garnet phase (red) in the phase map (figure

482   6e). The remaining points have a larger best match for clinopyroxe and are represented in

483   blue in the phase map. The curves along the horizontal and vertical axes in the joint

484   histogram represent the projections of the histogram onto the clinopyroxene and garnet

485   axes. Note that the clinopyroxene and garnet point clouds consist of overlapping blobs that

486   correspond to the individual grains in the microstructure. Overlap patterns obtained near

487   grain boundaries typically correspond to points in between the three major clusters of the

488   joint histogram. The color map in Figure 6e is obtained by merging f-i together with different

489   color values. The polar representation of the joint histogram in figure 6c provides a better

490   separation between the clinopyroxene and garnet phases and the melt phase, and was used

491   to obtain the binary maps in panels 6f tHough-6i. The lines limiting the fields between the

492   three phases were chosen at the local point density minimum, and for the clinopyroxene

493   garnet mixed patterns attributed a width of 0.5 rad of the polar angle.

494

495

23

496   **Sample 2.** The EBSD raw data of sample 2 were indexed with the OIM software (upper row in

497   figure 7), and using the DI routine (lower row in figure 7). Representative electron

498   backscatter patterns are displayed in figure 7 in the bottom row. The results are visualized

499   using the inverse pole figure (IPF) color scheme of OIM. The OIM data reveal more random

500   orientation pixels mainly along grain boundaries relative to other areas of the sample. In

501   contrast, the DI method returns grains that are all well delineated, and only a few grain

502   boundary points are indexing randomly (figure 7a versus c).

503   To obtain grain boundary trace/segment information, and thus the orientation of the

504   adjacent crystals, their disorientation and the best trace of orientation of the grain boundary

505   plane intersecting with the sample surface, the data sets must be free of any randomly

506   indexed pixels. This is however not a requirement if the user is only interested in simply

507   obtaining misorientation data, as there only the Euler angles of the adjacent grains are

508   necessary. Thus, the OIM data must undergo a cleanup procedure as described above (see

509   "Methods"). The raw data and cleaned data are presented in figures 7a,b respectively. The

510   spotted grains in figure 7a are indicative of the indexing ambiguities inherent to the OIM

511   analysis. In figure 7b, grain boundary segments, highlighted in white, can subsequently be

512   analyzed for twinning and disorientations between grains. To extract the same information

513   using the DI method, the grain boundaries are delineated using the ADP-map, shown in

514   figure 7d.

515   The noisy appearance of the phase map obtained using OIM in Figure 7a,b is a result of

516   incorrectly indexed (or un-indexed) patterns. However, using the DI approach in Figure 7c,d,

517   as there is always a largest dot product, no un-indexed points are observed. The need for a

24

518   post-indexing cleanup step is therefore removed. To evaluate the reliability of the DI routine,

519   and the conventional Hough-space based indexing, we compare the extracted disorientation

520   distributions with the expected random disorientation distribution calculated for

521   orthorhombic symmetry (Fig. 8). The disorientation distribution obtained from the DI map

522   agrees perfectly well with the calculated random distribution, considering the limited

523   number of grains analyzed. In contrast, the indexing routine using the OIM routine results in

524   a high fraction of 60°[100] pseudo-symmetry related neighboring sampling points (compare

525   Fig. 8b and Fig. 8c).

526

527   **Discussion**

528   This study investigates the potential of the DI approach, which allows for the indexing of

529   every EBSD pattern with an absolute value of confidence. If patterns from one phase receive

530   low dot product values during the first DI run, dictionaries for additional phases can be

531   calculated until all EBSD patterns can be assigned to a phase. The fact that there is always a

532   best match means that no patterns go unindexed, not even the overlap patterns near grain

533   boundaries for which the list of near matches contains the two different orientations on each

534   side of the grain boundary. The potential of developing unsupervised decision trees to

535   differentiate different pattern types, such as shifted background, as a result of a pore, noise

536   background, overlapping pattern at grain boundaries or grain interiors has been shown in

537   Chen et al. (2015) and is thus not repeated here. Note however, that unambiguous indexing

538   at interfaces or in relation with pseudo-symmetry is a clear advantage of the DI approach,

539   and this superiority becomes evident when evaluating the maps of figure 7 by displaying

25

540   their disorientation between grains and between OIM and DI maps displayed in figure 8. The

541   DI approach uses information from every pixel of an EBSP with equal weight; this is in strong

542   contrast to Hough-transform based methods, where only some peaks in Hough-space are

543   used for indexing. The Hough-transform based methods therefore, in principle, disregard

544   most of the information contained in weak Kikuchi bands or information contained in the

545   local absence of Kikuchi-bands. Consequently we identify the approach of using all

546   information of an EBSP equally as the source of success of the DI indexing technique.

547   The usage of all EBSP pixels equally is in our opinion also the cause for successful treatment

548   of overlapping patterns, for example at grain boundaries. Recently, Wright et al. (2015)

549   reported very powerful indexing results using neighbor pattern averaging with a re-indexing

550   (NPAR) post processing routine, which results in large indexing improvement. Nevertheless,

551   Wright et al. (2015) conclude: "The two methods produce comparable results except for the

552   presence of more mis-indexed points at the grain boundaries in the NPAR data than in the

553   dictionary data". We think that additionally it should be noted that NPAR is intrinsically

554   smoothing local information over several pixels at the expense of a decreased spatial

555   resolution, which is not the case for the DI approach. The strength of the DI approach in

556   comparison is therefore that it retains local information, such as small in-grain

557   misorientations, twin-lamellae or grain boundaries and interfaces with high accuracy and

558   precision, even at high noise levels. The DI routine results in maps in which all patterns are

559   indexed and attributed with an absolute error of indexing. Despite the fact that the resulting

560   maps of the DI approach have no data "holes", this does not necessarily mean that all

561   patterns have been positively identified, for example in the case where the actual phase was

562   not included in the matching procedure. The calculation of absolute errors is an important

563   innovation as it immediately indicates the necessity for reanalysis.

564   The DI approach leads to several improvements over the currently available standard

565   software solutions: (i) As the original data are saved, patterns and results can be reviewed

566   and revised at any time; (ii) indexing will always return a highest dot product, which allows

567   for an easy assessment on indexing quality and whether or not additional phases must be

568   considered. This is because the dot product value is normalized to the interval [-1,1], so that

569   the highest dot product also represents the confidence index. (iii) Absolute errors on the data

570   interpretation are ensured as the mean least square error on every indexing result is

571   obtained. (iv) Assumptions regarding the presence of pseudo-symmetries are obsolete for

572   the systems investigated (Figure 7). (v) No data interpolations in the form of clean-up

573   procedures with intrinsic assumptions are required. While this is uniquely great for the DI

574   approach, recent developments show how pure data interpolation can be overcome by using

575   EBSD pattern post-processing in OIM, where, in case of low pattern quality, the EBSPs at a

576   given point are averaged with the patterns of the neighboring points (Wright et al. 2015). For

577   the latter is must be noted that small variations in orientation are smeared out over several

578   pixels. (vi) As the entire original EBSD patterns are routinely saved, additional information

579   can be extracted. For example gray level distributions in the electron backscatter pattern are

580   influenced by the chemical composition of the sample. At high backscattering angles the

581   intensity of the Kikuchi lines increases with increasing mean atomic number. Therefore, maps

582   similar to BSE images can be calculated, by considering only those rows of an experimental

583   EBSP sensitive to chemical composition (in most setups the upper rows of an EBSP). Similar

584   approaches have also been included in the OIM software recently, where gray values of

585   various predefined regions of an EBSP are summed and displayed as a grayscale intensity

586   map (Wright et al. 2015).

587   The drawbacks of the DI method as compared to standard software solutions are: (i) The

588   relatively long dictionary computing time, which can amount to several days for low

589   symmetry crystal structures, depending on the number of experimental patterns to be

590   indexed. This limitation can be reduced by accelerating these computations on computer

591   clusters, by means of GPUs (graphical processing units), high-performance computers, or

592   shared memory platforms. . The current implementation of the DI approach uses both the

593   GPU platform using OpenCL as well as the shared memory architecture using OpenMP to

594   speed up the computations. An additional simplification which gives equivalent results

595   involves calculating the binned pattern directly using the correct values of scaled pattern

596   centers, sometimes referred to as x-star and y-star but assuming that the ``apparent"

597   physical detector pixel size is binning*δ, where δ is the true physical detector size. This

598   typically reduces the pattern computation time by an order of magnitude for 4x or 8x binned

599   patterns. It has been shown in Ram et al. (n.d.) that the accuracy of the indexing remains

600   unaffected even for an EBSPs which are 25x25 pixels. Use of highly binned patterns together

601   with using the apparent physical detector pixel size gives us another avenue for improving

602   the indexing rate of the DI approach without compromising with the quality of the final

603   results. (ii) The need to save all patterns for subsequent indexing; while disk space is

604   relatively inexpensive, managing large numbers of pattern files can become problematic;

605   furthermore, the DI method is memory intensive, especially as the commercial indexing

606   systems are not designed to save the patterns in compressed image formats and to transfer

607   the data quickly to memory. Nevertheless, this situation is quickly improving with the

608   incorporation of new data formats (e.g. .pat and .hdf5). Final orientation data can be further

609   analyzed using the commercial software such as OIM or HKL, or using the freely available

610   matlab tool box MTex (Bachmann et al. 2010), which allow for the calculation of

611   geometrically necessary dislocations, misorientations or specific twin-boundaries. Note that

612   the concept of determining GND is still debated and Zisman (2016) suggested an alternative

613   approach which would indeed allow determining GND from our data, especially with a DI-

614   calculated for higher angular precision.

615   We point out that, while collecting EBSPs with short acquisition times and small data sizes is

616   ideal for the comparison of different indexing routines – these parameters are neither the

617   optimal acquisition parameters for Hough-based indexing nor for the DI approach.

618   Finally, we summarize the discussion analogous to Tao and Eades (2005), who discuss the

619   problems attributed to Hough-transform based EBSD processing and mapping and comment:

620   ""Saving all of the data" seems a cure for everybody and everything" at least in EBSD-based

621   research.

622   **Implications**

623   **The importance of high quality EBSD indexing for the analysis of interface characteristics of**

624   **polycrystalline and multiphase rock/material samples**: Rocks consist of crystal grains

625   separated by phase and grain boundaries, generally interfaces. Their presence impacts the

626   bulk rock properties such as diffusivity, electrical conductivity, deformation (sliding), or

627   reactivity. Furthermore, the presence and distribution of melt fractions in the interfacial

628   network of rocks/materials strongly impact the bulk rock physical and chemical properties

629   (McKenzie 1989; Watson and Lupulescu 1993; Faul 1997; Schäfer and Foley 2002; Garapic et

630   al. 2013). The wettability of specific interfaces and thus, as a function of interface energy

631   may control melt extraction and percolation (Bagdassarov et al. 2000; Faul 2000). Here, we

632   demonstrate that spatially high resolved EBSD data obtained by the DI routine help to

633   minimize the individual bias of the extent of wettability by a quantitative evaluation of melt

634   distribution. Acquired EBSD data are also suited to determine whether or not melt fractions

635   are mobile, able to segregate and to be extracted from its host rock at upper mantle

636   conditions, provided high-spatial resolution EBSD data are available.

637   Grain boundary properties and structure relations are best revealed when examining grain

638   boundary plane orientation distributions (GBPD) and thus, internal surfaces (Saylor et al.

639   2003; Rohrer et al. 2004; Papillon et al. 2009; Marquardt et al. 2015). Coincident site lattice

640   (CSL) grain boundaries and grain misorientations instead are of negligible importance in

641   comparison (Randle 2002; Rohrer 2007). The grain boundary plane distribution is obtained by

642   using a stereological approach based on 2-D EBSD data (Saylor et al. 2004a). The

643   characterization of grain boundaries using EBSD data is however ultimately limited by the

644   indexing quality and clean up procedures of the EBSD data (Rohrer et al. 2004) as well as the

645   character and conditions of the grain boundaries (i.e. such as wet or dry). Pseudo-symmetric

646   indexing as required for forsterite may introduce grain boundary planes into a data set, or

647   even remove those if artificially cleaned. As quantified in this study, the pseudo-symmetric

648   relation of 60° misorientations around the common 100 direction is caused in the case for

649   olivine by the nearly hexagonal closed packed oxygen sub-lattice (Poirier 1975).

650   This study demonstrates that correct indexing at interfaces is crucial for interface distribution

651   studies and that indexing melt using EBSD will help to understand melt distribution in

652   partially molten rocks. Similarly, the investigation of grain boundary characteristics requires

653   high accuracy (and preferably precision) of indexing.

654   The DI approach overcomes long standing difficulties to index patterns of low quality,

655   including patterns affected by sample surface charging, low indexing rates, as well as

656   difficulties arising from pseudo-symmetric indexing. Therefore, we are convinced that future

657   EBSD-based work will greatly benefit from the DI approach. Examples for such are in

658   particular (i) the characterization of melt distribution in partially molten rocks, (ii) grain

659   boundary character distribution where minerals are affected by mis-indexing problems (e.g.

660   caused by pseudo-symmetry), and (iii) indexing of low-quality EBSD patterns (e.g. caused by

661   insufficiently polished surfaces of minerals/rocks/ materials).

662   The direct characterization of the melt distribution by the DI method would help to better

663   understand recent experimental studies on pre-melting at low-angle grain boundaries

664   (Levine et al. 2016).

860   Figure captions

861

862   **Figure 1.** Schematic of the dictionary indexing process. A Generalized Forward Projector

863   (GFP) model for EBSD (light blue box) is combined with a realistic detector and noise model

864   (yellow box) and a uniform sampling of orientation space (orange) to generate a pattern

865   dictionary (dark blue box), which consists of parts of the master pattern depicted in figure 2.

866   The experimental patterns (pink box) are then compared with the dictionary patterns using a

867   pattern matching engine (green box), in this case a simple dot product comparison. The

868   result is a set of indexed EBSD patterns (bottom green-filled box) which can then be analyzed

869   similar to standard EBSD data, e.g. using commercial software or MTex.

870

871   **Figure 2.** EBSD master patterns for (top row) forsterite, garnet, and enstatite, and (bottom

872   row) clinopyroxene; all patterns are represented as stereographic projections, with the

873   crystallographic a-axis oriented horizontally towards the right and the reciprocal c*-axis

874   normal to the projection plane. The projections for clinopyroxene show both the northern

875   (left) and southern (right) hemispheres; for the other structures, the two hemispheres have

876   identical projections.

877

878   **Figure 3.** Graph showing the dot product values obtained by multiplying an experimental

879   EBSP with the dictionary pattern versus the disorientation between the experimental EBSP

880   and the simulated EBSP. The indexing routine in the dictionary approach is based on a

881   ranking of similarity between experimental EBSP and simulated EBSP using computed dot

41

882   products $\widehat{v}_j . \widehat{w}_k$, where the experimental patterns are given by the vectors $\widehat{v}_j$ with $1 \leq j \leq$

883   N_e and the dictionary patterns by $\widehat{w}_k$ with $1 \leq k \leq N_d$. The largest dot product value

884   represents the highest similarity between experiment and simulation; plotted is the ranking

885   from large to small of each j's top 15 products or more. In green this is displayed for low

886   quality EBSP of forsterite; in blue for high quality EBSP of clinopyroxene and in red for garnet.

887   The assumption for the disorientation scale is that the dictionary finds the correct

888   misorientation.

889

890   **Figure 4.** Illustration of image processing prior to nearest neighbor similarity map calculation.

891   (a) Average dot-product (ADP) map for the raw background subtracted patterns, and b)

892   shows a histogram (red) for a background-subtracted EBSP outlined in red, along with the

893   EBSP and histogram after adaptive histogram equalization in blue and outlined in blue. (d)

894   ADP map after applying adaptive histogram equalization before calculating the average dot-

895   products. (d) Magnified region from (c), with an interesting region where backscatter

896   information of crystal and melt overlap. The lowest row, e) displays exemplary raw EBSPs.

897

898   **Figure 5.** Comparison of common measures of OIM and the DI-approach. In the first row

899   some measures of OIM are displayed. Pattern quality, judged by how easy Kikuchi bands can

900   be detected, a) OIM IQ-map; disorientation between indexed pattern b) OIM KAM-map; and

901   the confidence index, c) OIM CI-map. In the second row comparable measures used in the DI-

902   approach. d) EBSP image quality expressed through the Q parameter, e) inverse average dot

903   product ADP-map, f) highest dot product, g) KAM map obtained by using the average

904   orientation for the 20 highest dot products (20HDP), with a misorientation maximum of 10°.

905   h) ADP-map. i) orientation similarity map, OS-map.

906

907   **Figure 6.** Phase identification using different indexing routines. a) indexing using Hough-

908   transform based indexing in HKL, the map was acquired next to the map displayed in

909   d,e,f,g,h,I, using the same settings as for the later. 44% of pixels stay without a solution. Post

910   processing is largely prevented by the presence of the melt phase. b) Indexing by means of

911   DI. The dot product values of garnet and clinopyroxene are plotted versus each other. c) Plot

912   of the polar distance versus the polar angle determined using the DI approach. The three

913   phases can be clearly separated. d) average dot product map obtained from DI indexing.

914   Grain, phase and twin boundaries are nicely delineated. e) Phase identification in a 2D map

915   representation using the differentiation obtained from b and c respectively. Blue: cpx; Red:

916   Garnet, Yellow: Amorphous (melt) phase and white: wetted Grt-Cpx phase boundaries. f-i)

917   Dictionary indexing confidence index map (DI CI). Light colors correspond to high dot-

918   products, dark are low (i.e., poor or no pattern matches); the dot product for experimental

919   images vs. the cpx dictionary is displayed in f. g) Garnet DI CI, h) Melt pools DI CI, i) Grt-Cpx-

920   phase boundaries.

921

922   **Figure 7.** Comparison of OIM indexing (upper row) and data fitting using the dictionary

923   approach (lower row). In both examples the EBSP were indexed with forsterite being the only

924   phase. Representative EBSPs are depicted in the third row. a) OIM indexing, raw data, on the

925   left an enlargement of the data is shown. b) Cleaned OIM data set, highlighting the grain

926   boundaries in white. c) Same data set as in a, but indexed using the dictionary approach,

43

927   note the absence of randomly -indexed pixels in the data set and the consistency of indexing

928   across grain boundaries and in the crystal interior; examples are encircled in the enlargement

929   of a and c. d) Grain boundaries highlighted (dark) using the dictionary data. Displayed is the

930   average dot product map (ADP) that shows average dot product value for each pixel the of

931   the EBSD pattern with its four nearest neighbors. In the third row (e) the color legend and

932   typical EBSD patterns are displayed. The blow-ups of the panels a,b,c, and d are on the left

933   and right hand side of the respective pannels.

934

935   **Figure 8:** Disorientation distribution plots resulting from the different analyses approaches,

936   a) OIM raw indexing (red) and OIM after pseudo-symmetry correction (blue); b) dictionary

937   approach raw data (green), no second graph is displayed as no corrections apply to the

938   dictionary; c) discrepancy in indexing between DI and OIM displayed as disorientation

939   between the respectively indexed pixels. The disorientation between two pixels indexed

940   using the DI or Hough-transform based methods is minimal if the same or similar results are

941   obtained. Different indexing results of same pixels are related to pseudo-symmetric relations

942   as well as other issues such as the assignment of grain boundary pixels to one or the other
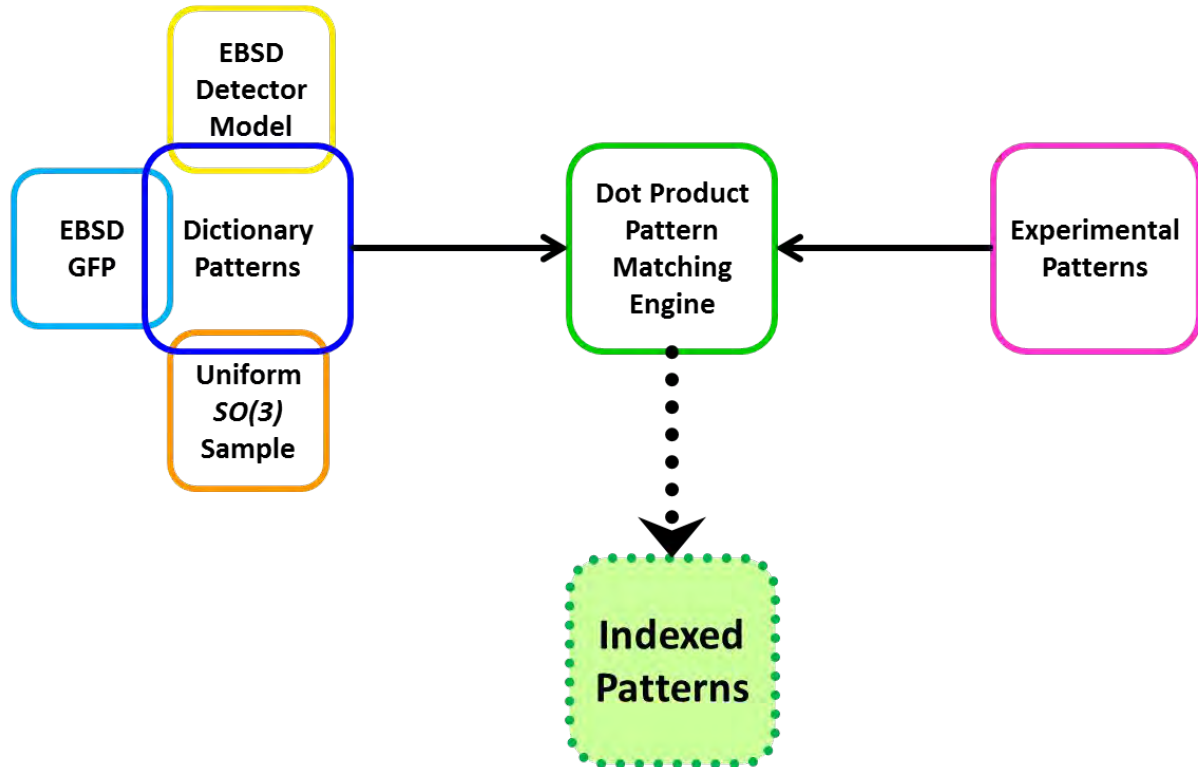

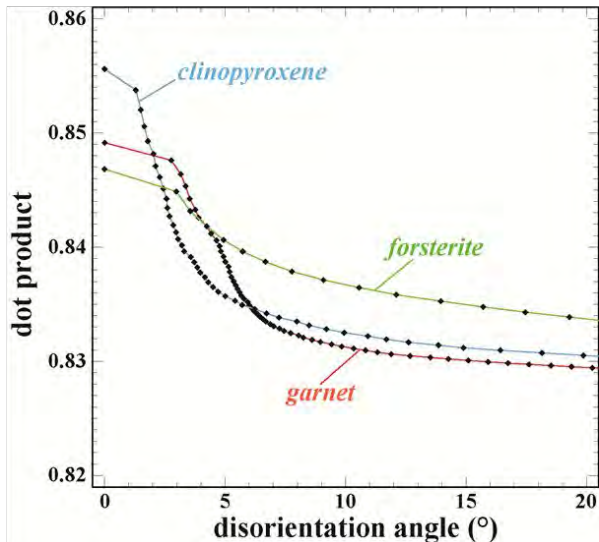

943   grain.
