8

9   **Abstract**

10   Efforts to map the vertical distribution of mafic and ultramafic igneous rocks in the Earth's crust and

11   uppermost mantle have long been hampered by the lack of precise geobarometers for the appropriate

12   mineral assemblages. The average pressure (avP) method (Powell and Holland 1994, Am Min 79, 120-

13   133) is a multiple-reaction approach that uses a least-squares minimization to average the pressures

14   derived from individual mineral equilibria, taking into account both their uncertainties and correlations.

15   We applied avP to a carefully selected database of published phase equilibrium experiments in dry to

16   H_2O-saturated, andesitic to basaltic and peridotitic systems at $P = 0.6–9.3$ kbar, $T = 940–1240$˚C, with

17   log fO_2 from NNO - 2.6 to NNO + 3.6 log units (where NNO is nickel-nickel oxide buffer). We made

18   minor modifications to the thermodynamic models of clinopyroxene, spinel and olivine in order to

19   improve the accuracy and precision of the results given by the avP method. Tests on the experimental

20   database, using the modified thermodynamic models and spinel + clinopyroxene + olivine +

21   plagioclase equilibria, showed that avP can reproduce the experimental P, within the calculated 1σ

22   uncertainties (0.9–2.6 kbar; 1.6 kbar on average), for 67% of the database. No systematic deviations of

23   the calculated pressure (P) with temperature (T) or mineral compositions are observed. Given the large

24   compositional range of the experimental database, these results suggest that the method can be applied

25   to any gabbroic, pyroxenitic or peridotitic rocks that contain the appropriate phase assemblage

26   clinopyroxene + olivine + plagioclase ± spinel. For assemblages equilibrated at P < 5 kbar, the

27   calculated P shows a slight dependence on T, which therefore needs to be well constrained in order to

28   keep the overall P uncertainties as low as possible. T can be estimated using either available

29   independently-calibrated geothermometers or a simple calculation routine suggested in this work.

30   Application of avP to gabbroic xenoliths from Dominica, Lesser Antilles, and to gabbroic and

31   peridotitic xenoliths from Wikieup, Arizona, demonstrates the ability of the method to produce precise

32   P estimates for natural assemblages equilibrated at both mid and lower crustal conditions respectively.

33   Depending on the errors on mineral composition, appropriateness of the T estimate and attainment of

34   equilibrium of the assemblage, P uncertainty for natural rocks is ≤ 1.0 kbar. Such level of precision can

35   help discriminating rival petrogenetic processes in subduction zone, intra-plate and mid oceanic ridge

36   settings.

40   **Introduction**

41   Estimating the pressure (P) and temperature (T) of formation of mafic and ultramafic igneous rocks is a

42   fundamental step in studying the evolution of magmatic systems and the thermal and lithological

43   structure of the crust and crust-mantle transition zone. Developing accurate and precise

44   thermobarometric methods for such rocks is therefore critically important. Conventional methods use

45   phase compositions combined in either empirical or theoretical formulations to derive expressions for P

46   and T, with the fundamental assumption that the assemblage of interest attained equilibrium.

47   Commonly used geothermometers and geobarometers for gabbroic and peridotitic rocks are based on

48   single reactions between mineral end-members, often derived by simple regressions of experimental

49   data. Examples include two-pyroxene thermometers (e.g., Wells 1977; Putirka 2008) and barometers

50   (Putirka 2008), olivine-pyroxenes-plagioclase barometers (e.g., Fumagalli et al. 2017), hornblende-

51   plagioclase thermobarometers (e.g., Holland and Blundy 1994; Molina et al. 2015) and magnetite-

52   ilmenite thermometers (e.g., Ghiorso and Evans 2008). Empirical methods based on the composition of

53   a single mineral phase, such as clinopyroxene barometers (e.g., Nimis 1995; Putirka 2008) and

54   amphibole thermobarometers (e.g., Ridolfi and Renzulli 2012) are also available for gabbroic as well

55   as, basaltic and andesitic rocks. Mineral-melt thermobarometers potentially produce precise pressure

56   and temperature estimates (Falloon et al. 2007; Putirka 2008; Putirka 2016a; Neave and Putirka 2017),

57   but their application to gabbroic or peridotitic rocks is limited to assemblages containing melt in

58   equilibrium with the solid phases (interstitial melt or trapped melt inclusions).

59   For any given plutonic suite, a barometer or thermometer should meet the following conditions: i)

60   sufficient precision to discriminate between rival petrogenetic processes, ii) applicability over the P-T

61   range of interest, iii) calibration for the compositions of interest, iv) consistency across the entire suite.

62   Depending on the assemblage, criterion (i) can often be met for temperature, as model errors can be as

63   low as 40 ºC (e.g., Putirka 2008), which is small relative to the range of formation of mafic/ultramafic

64   plutonic rocks (800–1300 ºC). However, for existing barometers that are applicable to subsolidus

65   gabbroic assemblages (e.g., two-pyroxene or single-clinopyroxene barometers of Putirka 2008, single-

66   amphibole barometer of Ridolfi and Renzulli 2012), typical model errors are 3–4 kbar (inferred from

67   experimental data not used in the calibration; see Putirka 2008, 2016b and Erdmann et al. 2014 for a

68   review). This is unacceptably high considering the typical pressure range to be investigated (e.g., < 7

69   kbar for island arcs and intra-oceanic settings).   For empirical or semi-empirical single-reaction

70   thermobarometers, condition (ii) is usually met, as calibrant phase equilibrium experiments generally

71   cover a wide range of P and T (e.g., 0–20 kbar, 800–1400ºC). Condition (iii) is particularly critical

72   when adopting empirical or semi-empirical thermobarometry, because relationships that are too

73   simplified or that have no thermodynamic basis become unreliable when applied outside the range of

74   the calibration data. For the same reason, some empirical thermobarometers may be sensitive to the

75   buffering effect of phases that are not involved in the reaction, but are present in the assemblage,

76   hampering the application to natural samples with phase assemblages that differ from those in the

77   calibration dataset. This issue may be particularly important when single-phase empirical

78   thermobarometers calibrated using *suprasolidus* (i.e. melt-present) experiments (e.g., Ridolfi and

79   Renzulli 2012) are applied to plutonic rocks equilibrated at *subsolidus* (i.e. melt-absent) conditions.

80   Finally, condition (iv) may be difficult to meet when the rock suite includes samples with different

81   mineral assemblages, requiring the adoption of different, potentially inconsistent, single-reaction

82   thermobarometers calibrated on different experimental datasets.

83   A potential solution that fulfils all of the above conditions for pressure determination is multiple-

84   reaction barometry, employing an internally consistent dataset of thermodynamic data for mineral end-

85   members (e.g., Berman 1988; Holland and Powell 1998, 2011), along with a set of activity-

86   composition (*a-x*) relations calibrated for use with the same end-member dataset[1]. The multiple-

87   reaction method allows all of the P and T information in a mineral assemblage to be used

88   simultaneously, provided the necessary thermodynamic models exist, via an independent set of

89   reactions among the end-members of the phases (Berman 1991; Gordon 1992; Powell and Holland

90   1988, 1994, 2008). End-member thermodynamic data and activity-composition (*a-x*) relations are now

91   available for the majority of rock-forming minerals of the crust and shallow mantle (e.g., Ghiorso and

92   Sack 1995; Holland and Powell 2011; Diener et al. 2007; Green et al. 2007, 2012, 2016; Gualda et al.

93   2012; White et al. 2014; Jennings and Holland 2015), thus potentially allowing the method to be

94   applied consistently to rock suites across a wide range of mineralogy and composition.

---

[1] We use the term 'thermodynamic model' to refer to both the thermodynamic properties of the end-members and the constituent *a-x* relations

4

95   A single reaction among the end-members of phases is sufficient to calculate the value of P at given

96   T. However, in a robust application of multiple-reaction barometry, there are several reactions forming

97   an independent set, and the P values are statistically over-determined. Owing to the uncertainties in

98   thermodynamic models and in analysed mineral compositions, the reactions do not, in general, intersect

99   at the same $P(T)$. Therefore a statistical approach is needed to calculate the optimal P. Such an

100   approach must be weighted by the uncertainties affecting each reaction in the independent set, and this

101   weighting must also take into account the correlated influence of these uncertainties on reactions that

102   share end-members (Powell 1985; Powell and Holland 1994). The average P (avP) method (Powell and

103   Holland 1988, 1994, 2008), is one of the few available algorithms for multiple-reaction

104   thermobarometry that uses a rigorous statistical approach to handle both uncertainties *and* correlations.

105   The algorithm is accessible via the software THERMOCALC, using the Holland and Powell (1985, 1990,

106   1998, 2011) internally consistent dataset of end-members and, in principle, any suitably encoded *a-x*

107   relations with the modified regular solution formulations described in Powell and Holland (1993) and

108   Holland and Powell (2003).

109   The avP algorithm in THERMOCALC has historically been applied to metamorphic rocks, and the

110   development of *a-x* relations suitable for their use has concentrated on the metamorphic domain.

111   However, following the work of Jennings and Holland (2015) and Green et al. (2016), a set of *a-x*

112   relations is, for the first time, available for the phases expected in hydrous igneous rocks under crustal

113   and upper mantle conditions. Given the potential of avP to fulfil all the conditions for optimal

114   geobarometry, we evaluated the accuracy of the method and accompanying *a-x* relations for mafic and

115   ultramafic rocks using a dataset of phase equilibrium experiments in basaltic and peridotitic systems,

116   together with well-equilibrated natural samples, as a test case.

117   **Methodological overview and rationale**

118   Our aim is to develop a procedure for reliably applying multiple-reaction barometry to crustal-depth

119   mafic and ultramafic igneous rocks. A database of phase equilibrium experiments (Supplementary

120   Material 1) was used to evaluate the results obtained with THERMOCALC's avP algorithm (Powell and

121   Holland 1988, 1994, 2008) and a selection of published thermodynamic models for mineral phases.

122   The thermodynamic models were then refined, where necessary, to minimise systematic discrepancies

123   between the avP calculations and the experimental database. Prior estimates of T and analytical or

124   model uncertainty were explored, both for the experimental database, and for natural samples. Our

125   work focused on rocks containing the assemblage SCOlP (see Table 1 for abbreviations). This

126   assemblage is common in mafic and ultramafic plutonic rocks from a variety of tectonic settings, and

127   appears in a relatively large number of experimental runs. We further tested avP calculations using the

128   sub-assemblage COlP. This yields only three independent reactions, compared with six for SCOlP, and

129   is therefore potentially less robust. However, COlP can be applied to a larger number of experiments

130   and natural samples, including plagioclase peridotites.

131   Refinement of the thermodynamic models allows the avP approach to satisfy criteria (i) to (iii)

132   above. Regarding criterion (iv), the method is devised such that it is possible to apply mutually

133   consistent barometers across a suite of rocks, simply by adding further sets of well-calibrated a-x

134   relations to those for olivine, clinopyroxene, plagioclase and spinel, using the same internally-

135   consistent dataset of end-member thermodynamic properties (Holland and Powell 2011).

136   Supplementary Material 2 describes how to obtain software and input files for applying the avP

137   approach to SCOlP and COlP assemblages, and provides an example calculation.

Experimental database

139   We assembled a database of published phase equilibrium experiments in natural andesitic to basaltic

140   and peridotitic systems whose run products contain, at least, olivine, clinopyroxene and plagioclase.

141   Some experimental datasets were excluded, despite containing the right assemblage, either because (i)

6

142   the experiments show clear evidence of disequilibrium (e.g., large compositional inhomogeneity of the

143   run products, significant Fe loss), or (ii) run duration was very short (i.e. < 2 hours) or (iii) mineral

144   compositions were not reported. A reference list of experiments that satisfied these requirements is

145   reported in Supplementary Material 1 and their *P-T* conditions are shown in Figure 1. Clinopyroxenes

146   in most of the experiments at $P \geq 9$ kbar and $T \geq 1150°C$ have low Ca contents (≥ 0.38 atoms per

147   formula unit, apfu; Bartels et al. 1991; Draper and Johnston 1992; Kinzler and Grove 1992; Fig. 2a).

148   The closure of the solvus separating low- and high-Ca pyroxene compositions is difficult to capture

149   accurately in *a-x* modelling and, moreover, such low-Ca clinopyroxenes are rare in natural igneous

150   rocks. We therefore excluded the experiments containing these clinopyroxenes from the dataset.

151   Additionally, clinopyroxenes from atmospheric pressure experiments (0.001 kbar) show a range of

152   tetrahedral aluminium ($Al^{IV} = 2 - Si$ [apfu]) contents that exceeds that at higher pressures (Fig. 3),

153   suggestive of a complex cation partitioning for 1-atm clinopyroxenes. Existing geobarometers

154   involving Al- and Na-in-clinopyroxene components systematically fail to predict pressure for 1-atm

155   experiments. This has been ascribed to Na-loss during the experiment (Putirka 2008), although,

156   conversely, Mollo et al. (2010) showed that fast-growing clinopyroxene crystals contain excessive Na

157   and Al, compensating for depletions in Si, Ca and Mg relative to the equilibrium composition.

158   Considering that some equilibria used in this work involve Al and Na partitioning, we therefore

159   removed all 1-atm experiments from the avP dataset. Additional filtering based on the quality of

160   microprobe analyses and possible presence of aberrant data (see Supplementary Material 1) yielded a

161   final dataset of 209 experiments with the COlP assemblage, of which 62 also contain the SCOlP

162   assemblage.

163   The conditions covered by the refined experimental database are $P = 0.5–9.3$ kbar, $T = 935–1240°C$

164   (Fig. 1) and log fO_2 from NNO - 2.6 to NNO + 3.6 log units. Compositions of olivine, spinel,

165   clinopyroxene and plagioclase are shown in Fig. 2. Olivines are almost pure solid solutions of forsterite

7

166 and fayalite, with only minor or trace amounts of Ca and Mn components (Ca < 0.025 apfu; Mn <

167 0.024 apfu). Plagioclases are solid solutions of albite and anorthite, with only minor amounts of K (<

168 0.12 apfu) and Fe$_{tot}$ (< 0.09 apfu) components. Spinels show a wide range of composition including

169 magnetites, ulvospinels and spinels sensu-stricto, with variable amounts of Cr (Fig. 2c) and mg# in the

170 range 0.11-0.89. Clinopyroxenes are augites with variable Al (0.08–0.39 apfu) and Ti (0.00–0.10 apfu)

171 and low Na (0.01–0.08 apfu). The 62 experiments containing the subset SCOlP cover roughly the same

172 range of P-T conditions and mineral compositions (e.g., Figs. 1 and 2a,b), with log fO$_2$ from NNO -0.1

173 to NNO + 3.6.

Average-Pressure calculations: methodology

Overview of the avP method

176 An optimal value of P, $\overline{P}$, may be found by least-squares averaging of multiple independent phase

177 equilibrium constraints, each of which can be formulated as a reaction between end-members. To find

178 the optimal value is not simply a matter of averaging the values of the P_r, the pressures obtained from

179 each reaction r in the set, because some end-members appear in more than one reaction. If the pressures

180 of the reactions are adjusted to coincide at $\overline{P}$, the implication is that the calculated chemical potentials

181 of the end-members are being adjusted. Adjustments to chemical potentials must be applied

182 consistently across each of the end-member reactions, meaning that the reactions must be moved in a

183 suitably correlated way in P space in order to coincide at $\overline{P}$. The approach is most powerful if applied

184 via using a set of fully thermodynamic models for the phases, in which the chemical potentials of end-

185 members are constructed from parameters representing other physical properties, such as standard

186 enthalpies, within some uncertainty. In this case, the correlated adjustments to the P_r required to

187 achieve coincidence at $\overline{P}$, can be made by adjusting the end-member properties, based on a covariance

188 matrix that is known *a priori*. The method amounts to 'least-squares adjustment of indirect

8

189   observations' (e.g. Mikhail 1976). Such a method, the avP algorithm, is described in detail by Powell

190   and Holland (1988, 1994, 2008), and exploits the Holland and Powell (1990, 1998, 2011) dataset of

191   end-member thermodynamic properties, combined with a set of a—x relations for each solid solution to

192   describe the thermodynamics of mixing (Gordon 1992 discussed a similar procedure). The TWEEQU

193   thermobarometric method of Berman (1991) is of the same type, but does not account for the

194   correlations in the adjustments applied to the P_r.

195   A statement of equilibrium for each multiphase reaction, r, can be written as

196    $\sum_i v_i \mu_i = \sum_i v_i \mu_i^0 + \mathrm{R}\, T \ln K_r = \Delta G_r^{\circ} + \mathrm{R}T\ln K_r = 0,$ (1)

197   where, for end-member i in a phase j of specified crystal structure, v_i is the reaction coefficient, μ_i is

198   the total chemical potential and μ_i^0 is the chemical potential of the pure end-member at $P,\ T$. ΔG_r° is the

199   Gibbs free energy difference in kJ for the reaction among the pure end-members, R is the gas constant

200   (0.0083144 kJ/K·mole) and K_r is the equilibrium constant, which is given by

201    $K_r = \prod_i (a_i)^{v_i},$ (2)

202   a_i being the activity of end-member i.

203   The avP algorithm, as implemented in THERMOCALC (Powell and Holland 1988), finds the activities

204   of end-members given the observed compositions of the phases, at a likely P_0 and T_0 (initial estimates

205   of pressure and temperature), to compute each equilibrium constant K_r. Taking the corresponding

206   expression for ΔG_r° from the Holland and Powell (1985 1990, 1998, 2011) dataset, it linearises

207   expression (1) at T_0, P_0, to form the equation from which P is obtained (Fig. 4):

208    $a + b\ T_0 + c\ P + \mathrm{R}T_0\ln K_r = 0$ (3)

209   The a, b and c terms represent the end-member enthalpy, entropy and volume changes, ΔH_r, $-\Delta S_r$ and

210   ΔV_r, respectively, for the reaction.

211   Uncertainties in equation (3) are derived from uncertainties in the properties of individual end-

212   members involved in the reaction. Only the enthalpies and activities of the end-members are considered

9

213   to be uncertain, since the Holland and Powell dataset treats end-member entropies and volumetric

214   properties as exact. The uncertainties in the end-member enthalpies are correlated with each other, and

215   their standard deviations and correlation coefficients are extracted from the Holland and Powell dataset.

216   The uncertainties in the activities of end-members are assumed to be independent of each other, and are

217   propagated through from (i) the analytical uncertainties in the compositional variables and (ii) the

218   uncertainties in the a-x relations, treated simply as uncertainties in the values of $W_{(m,n)}^{j}$.

219   As described in Powell and Holland (1988), the uncertainties in the enthalpies and activities of end-

220   members can be converted into uncertainties on the a and $\ln K_r$ terms of equation (3), taking into

221   account the reaction coefficient of each end-member. A full covariance matrix can ultimately be

222   derived, describing the uncertainties and correlations among the estimates of P from each of the

223   independent reactions (P_r).

224   Using the reactions and the corresponding covariance matrix, the avP algorithm finds an optimal

225   least-squares average of the P_r values, $\overline{P}$, with a well-defined uncertainty $\sigma_{\overline{P}}(T_0)$. Figure C2 from

226   Powell and Holland (1988) illustrates graphically how two correlated pressures (P_r) are combined to

227   give $\overline{P}$.

228   A number of diagnostic values are displayed following the avP procedure (see Supplementary

229   Material 2 and Powell and Holland, 1994), to assist meaningful application of the method. The

230   diagnostic value σ_{fit} is particularly helpful, providing a measure of how appropriately the pressure

231   information in the independent set of reactions can be combined. If σ_{fit} lies within the cut-off value

232   provided by the χ^2 test, representing 95 % confidence, then it is reasonable to assume that the selected

233   phases are indeed in thermodynamic equilibrium, given realistic uncertainties in the mineral analyses

234   and thermodynamic models.

235   **Independent reactions used in this work**

236   For each of the two assemblages (SCOlP and COlP) considered, we specified the independent set of

237   reactions to be used by the avP algorithm. These were chosen to have generally low uncertainties in

238   their individual pressure estimations, Pr, implying that they are sensitive to pressure, and also to lie

239   reliably within 20 kbar of the experimental pressures during model refinement. The choice of

240   independent reactions affects the calculated $\overline{P}$, but the variation in $\overline{P}$ is of the order of $\sigma_{\overline{P}}$. For the

241   assemblage SCOlP, the selected reactions are (see example in Supplementary Material 2 for ΔH_r, ΔS_r

242   and ΔV_r for each reaction):

243   r1)   cenh   +   cats   =   fo   +   an
244              $Mg_2Si_2O_6 + CaAl_2SiO_6 = Mg_2SiO_4 + CaAl_2Si_2O_8$

245   r2)   cfs   +   cats   =   fa   +   an
246              $Fe_2Si_2O_6 + CaAl_2SiO_6 = Fe_2SiO_4 + CaAl_2Si_2O_8$

247   r3)   cenh   +   jd   =   fo   +   abh
248              $Mg_2Si_2O_6 + NaAlSi_2O_6 = Mg_2SiO_4 + NaAlSi_3O_8$

249   r4)   cenh   +   2 cats   =   di   +   an   +   sp
250              $Mg_2Si_2O_6 + 2\ CaAl_2SiO_6 = CaMgSi_2O_6 + CaAl_2Si_2O_8 + MgAl_2O_4$

251   r5)   cenh   +   jd   +   2 herc   =   fa   +   abh   + 2 sp
252              $Mg_2Si_2O_6 + NaAlSi_2O_6 + 2\ FeAl_2O_4 = Fe_2SiO_4 + NaAlSi_3O_8 + 2\ MgAl_2O_4$

253   r6)   2 cfs   +   2 acm   +   herc   =   2 fa   +   2 abh   +   mt
254              $2\ Fe_2Si_2O_6 + 2\ NaFeSi_2O_6 + FeAl_2O_4 = 2\ Fe_2SiO_4 + 2\ NaAlSi_3O_8 + Fe_3O_4$

255   where the number of independent reactions is equal to $s - c$, with s being the number of end-members

256   and c the number of components involved in mixing (see Table 2).

257   For COlP, an independent set contains three reactions. The natural choice is simply those of the set

258   of reactions r1—r6 that do not involve end-members of spinel solid solution, i.e., reactions r1, r2 and

259   r3.

260   **Thermodynamic models**

261   We employed the internally consistent thermodynamic dataset of Holland and Powell (2011; version

262   6.3, generated 29 March, 2016), and an initial selection of published a—x relations that are appropriate

11

263   for use with this dataset: the models for plagioclase, clinopyroxene, olivine and spinel were taken

264   respectively from Holland and Powell (2003), Green et al. (2016), Hackler and Wood (1989), and

265   Bryndzia and Wood (1990). Specifically, these a—x relations are regular solution models (one-

266   parameter Margules solutions), with mixing on sites, allowing for asymmetry introduced via a van Laar

267   parameter applied to each end-member.

268   During our development of a procedure for application of avP to igneous rocks, a major requirement

269   was to make modifications to the thermodynamic models (end-member properties and/or a—x

270   relations) in order to achieve accurate estimation of $\overline{P}$ values for our experimental database. Many of

271   these modifications involved the adjustment of end-member Gibbs energy functions from the dataset,

272     $G^{ds}(P,T)$, by functions $\Delta G^{mod}(P,T)$, such that for end-member i, $G_i(P,T) = G_i^{ds}(P,T) + \Delta G_i^{mod}(P,T) =$

273     $G_i^{ds}(P,T) + a + b\,T + c\,P$ (the constants a, b and c may be considered to represent enthalpy, entropy

274   and volume terms respectively). Additionally we made minor structural changes to the a—x relations,

275   and adjusted some of the interaction energies, $W(m,n)$.

276   By repeatedly assessing the results of avP run on the experimental database as described below, we

277   adopted the following thermodynamic models for clinopyroxene, olivine and spinel. We did not modify

278   the Holland and Powell (2003) models for plagioclase, an asymmetric solution between high-albite,

279   anorthite and sanidine. Model end-members are listed in Table 2, and a full description of the a—x

280   relations and end-member thermodynamic data can be found in the Supplementary Material 3.

281   **Clinopyroxene.** The starting point for the clinopyroxene a—x relations was the 'augite model' of

282   Green et al. (2016) that entails mixing of [Mg, Fe^{2+}, Al, Fe^{3+}] on the M1, [Na, Ca, Mg, Fe^{2+}] on the

283   M2, and [Si, Al] on the tetrahedral sites. The end-members high-temperature clinoenstatite (cenh) and

284   clinoferrosilite (cfs) do not appear in the Holland and Powell (2011) dataset, but are constructed by

285   adding $\Delta G_i^{trans}(P,T)$ terms to the Gibbs energy functions for ortho-enstatite (en) and ortho-ferrosilite

286   (fs) respectively (Green et al. 2016), where $\Delta G_i^{trans}(P,T)$ represents the Gibbs energy change of the

12

287   *Pbca—C2/c* transition. The model incorporates order-disorder of Fe^{2+}-Mg across M1 and M2,

288   expressed via the proportions of an end-member fmc, $Fe^{M2}Mg^{M1}Si_2O_6$. Like the cenh and cfs end-

289   members, the fmc end-member does not appear in the dataset, but has a Gibbs energy function that can

290   be expressed as ½ $(G_{cenh}(P,T) + G_{cfs}(P,T)) + \Delta G_{fmc}^{od} = $ ½ $(G^{ds}_{en}(P,T) + G^{ds}_{fs}(P,T) + \Delta G_{en}{}^{trans}(P,T) + $

291    $\Delta G_{fs}{}^{trans}(P,T)) + \Delta G_{fmc}^{od}$, where ΔG_{fmc}^{od} is the Gibbs energy change of ordering to form fmc from a

292   disordered 1:1 mixture of cenh and cfs. The model also includes Si-Al order-disorder on the tetrahedral

293   site, but whereas in Green et al. (2016) this order-disorder was expressed explicitly, by including both

294   an ordered and a disordered Ca-tschermaks end-member in the solid solution, we here made a minor

295   simplification by replacing the ordered and disordered Ca-tschermaks end-members with a single end-

296   member, cats, from the Holland and Powell (2011) dataset, for which the thermodynamic properties

297   reflect disordering with temperature. This makes negligible difference to the calculations.

298   Three problems that emerged during testing of the avP procedure were linked to the clinopyroxene

299   model:

300   1)   Calculations on the COlP assemblage tended to produce $\overline{P}$ estimates that exceeded experimental

301   pressures by ~5 kbar.

302   2)   The avP diagnostics (see Supplementary Material 2) for the calculations on the SCOlP assemblage

303   suggested that the clinopyroxene end-members Ca-tschermaks and jadeite were particularly likely

304   to exhibit large, uncertainty-normalised residuals in activity, *e**, and that cenh strongly influenced

305          $\overline{P}$.

306   3)   When $\overline{P}$ was calculated over a range of T_0, values of σ_{fit} and $\sigma_{\overline{P}}$ were typically smaller for small

307   values of temperature, with minima occurring at temperatures $< T_{exp}$. This showed that the models'

308   temperature-dependences were poorly calibrated.   This is a significant observation since the

309   method of calculating $\overline{P}$ at multiple T_0 may be used to estimate the equilibration temperature of a

310   sample, as discussed below.

13

311   In response to problem 3), we investigated the model reaction Mg_2SiO_4 (fo) + $Fe_2Si_2O_6$ (cfs) = Fe_2SiO_4

312   (fa) + $Mg_2Si_2O_6$ (cenh), which is not included explicitly among our reactions, but appears implicitly

313   since it is obtained by subtracting r2 from r1. Taking both our own database and that of Loucks (1996),

314   we recalibrated the clinopyroxene and olivine models, treating fo + cfs = fa + cenh as a single-reaction

315   thermometer. The key changes made to the clinopyroxene model through this approach were to

316    $\Delta G_{cen}^{tran}(P,T)$ and $\Delta G_{cfs}^{tran}(P,T)$, which were recalibrated while preserving their fit to the estimated

317   transition curves in P—T space (taken from Boyd et al. 1964, as interpreted by Gasparik 1990, for

318   enstatite-clinoenstatite; and from Lindsley 1981, for ferrosilite-clinoferrosilite). We also decreased the

319   value of $\Delta G_{fmc}^{od}(P,T)$ from −4.4 kJ mol^{-1} to −6.5 kJ mol^{-1}. Minor adjustments were made to the

320   relatively well-known interaction energies in the CaO—FeO—MgO—SiO$_2$ system, $W_{(di,cfs)}$, $W_{(di,fmc)}$,

321    $W_{(cenh,cfs)}$, and $W_{(cfs,fmc)}$, while respecting the experimental constraints placed on them (Turnock and

322   Lindsley 1981; Lindsley 1983; see Green et al. 2016). The revised values are considered to be better

323   constrained than the originals. The modified models continue to predict temperatures for the fo + cfs =

324   fa + cenh reaction with a large scatter, but now with a reasonable standard error of estimate of ±71ºC.

325   We made further adjustments to many of the less well-constrained interaction energies, with

326   reference to both the fo + cfs = fa + cenh reaction and the results of avP calculations on the

327   experimental database. These adjustments involved reducing the size of the interaction energies by

328   ~40%. In modifying the interaction energies, we treated them as falling into groups that should retain

329   similar values: (1) the W([cenh,cfs,fmc],[jd,acm]) parameters (notation indicates interaction energies

330   between each of the end-members in the first square brackets with each of the end-members in the

331   second); (2) the W([cenh,cfs,fmc],[cats]) parameters; (3) the W([jd,acm],[cats]) parameters.

332   W([di],[cats]) was adjusted independently. These modifications greatly reduced the excessive avP

333   estimates for COlP (Fig. 5b), and removed the high residuals associated with a_{cats} and a_{jd} when SCOlP

334   is used. Furthermore, values of σ_{fit} for the experiments typically decreased, with fewer experiments

14

335   failing the χ^2 test; this was a valuable indication that the adjustments tended to make the models, as a

336   set, predict a more mutually consistent set of independent reactions given the experimental phase

337   compositions.

338   Individual changes made to the poorly-constrained interaction energies should not necessarily be

339   regarded as improvements to the original *a—x* relations, since avP in general demands less accurate *a-x*

340   relations than the forward-modelling calculations for which the Green et al. (2016) clinopyroxene

341   model was developed. However it is interesting that a much less non-ideal model was required to

342   produce good avP results, especially considering that the pressure information in reactions r1-r3 is

343   related primarily to formation of aluminous pyroxene from plagioclase (i.e. Ca-tschermak + Quartz =

344   Anorthite). The thermodynamics of the key pyroxene and plagioclase end-members in the Holland and

345   Powell (2011) dataset, including the crucial volumetric parameters, are expected to be well known.

346   **Olivine.** We initially followed Jennings and Holland (2015) in adopting a simple symmetric model for

347   a forsterite—fayalite solid solution, with Mg—Fe mixing on two identical M sites, as per Hackler and

348   Wood (1989), with $W(\mathrm{fo,fa}) = 8$ kJ mol^{-1}. During refitting of the reaction fo + cfs = fa + cenh, we found

349   it necessary to introduce order-disorder, via an ordered end-member $\mathrm{Fe^{M1}Mg^{M2}SiO_4}$ (olfm; compare

350   with discussion of ordered end-member fmc above; see also Supplementary Materials 3), with a Gibbs

351   energy function given by $G_{\mathrm{olfm}}(P,T) = \frac{1}{2} \{(G_{\mathrm{fo}}(P,T) + G_{\mathrm{fa}}(P,T)\} + \Delta G^{\mathrm{od}}_{\mathrm{olfm}}(P,T)$, and $\Delta G^{\mathrm{od}}_{\mathrm{olfm}}(P,T) = (-8$

352    $+ 0.003\ T + 0.02\ P)$ kJ mol^{-1}. This expression yields -3.8 kJ mol^{-1} at 1100ºC and 5 kbar, and remains

353   negative, i.e. favouring ordering, below 2300ºC within the pressure range of interest. $\Delta G^{\mathrm{od}}_{\mathrm{olfm}}(P,T)$ is

354   thus of a physically plausible size over the *P-T* range of interest, comparable with $\Delta G^{\mathrm{od}}_{\mathrm{fmc}}(P,T)$. We

355   stress, however, that our calibration does not provide unique constraints on the *a*, *b* and *c* terms of

356    $\Delta G^{\mathrm{od}}_{\mathrm{olfm}}(P,T)$ and they should be considered essentially as fit parameters, compensating for other

357   difficulties in modelling Fe-Mg exchange between olivine and clinopyroxene in natural systems.

15

358   **Spinel.** Jennings and Holland (2015) used the spinel a—x relations of Bryndzia and Wood (1990), in

359   the system MgO—FeO—Fe_2O_3—Al_2O_3—Cr_2O_3, in which all cations mix on three identical sites. Such

360   a model greatly simplifies the mixing behaviour of spinel, by neglecting cation and magnetic

361   disordering. Nevertheless, Bryndzia and Wood (1990) applied it successfully to oxy-barometry of

362   spinel peridotites, and it performed convincingly in the forward calculations of Jennings and Holland

363   (2015), also on peridotite. Therefore we initially adopted the Bryndzia and Wood (1990) a—x relations,

364   extended to include TiO_2 by T.J.B. Holland (personal communication; see Supplementary Material 3).

365   For the majority of experiments that contained magnetite rather than Cr/Al-spinel, we found that avP

366   calculations with SCOlP had a tendency to underestimate experimental pressures, even when

367   calculations with COlP tended to overestimate them. Modifications to the clinopyroxene model, as

368   described above, reduced $\overline{P}$ estimates for both assemblages. To overcome this discrepancy between the

369   assemblages, and following the observation that the end-members sp and herc showed large

370   uncertainty-normalised residuals in activity (as suggested by the avP diagnostics), we were obliged to

371   add large $\Delta G_i^{mod}(P,T)$ terms, of 5 kJ mol^{-1}, to the sp and herc end-members. These terms may be

372   crudely compensating for the highly simplified form of the spinel a—x relations, and indeed any

373   unidentified weaknesses elsewhere in the set of thermodynamic models, that compensate for each other

374   in COlP. Additionally, we found that pressures for experiments containing Cr/Al-spinel were routinely

375   overestimated. We were able to prevent this by adjusting the value of $W_{sp-picr}$ from 39 to 23 kJ mol^{-1},

376   and that of $W_{herc-picr}$ from 27 to 16 kJ mol^{-1}. The modifications also allowed most of the experiments to

377   pass the χ^2 test, whereas, using the original spinel model, most of SCOlP calculations failed, with σ_{fit}

378   $\gg 1.49$.

379   **Inputs for avP: compositions, uncertainties, P_0 and T_0**

380   Mineral formulae for the SCOlP/COlP phases in the experimental runs and natural samples were

381   recalculated from the compositions determined by electron microprobe. Iron was assumed to be all

16

382   ferrous in olivine and all ferric in plagioclase. Fe^{3+} in clinopyroxene and spinel was calculated from

383   stoichiometry following the method of Droop (1987). Mineral formulae were then converted into

384   compositional variables suitable for the a—x relations (Supplementary Material 2). THERMOCALC

385   (Powell and Holland 1988) version 3.47i was used to run the avP algorithm on these data, generating a

386   value of $\overline{P}$ based on each assemblage for each experiment. The results obtained from the avP algorithm

387   are sensitive to the relative size of uncertainties specified for the compositional variables, and also to

388   those applied to the interaction energies, $W_{(m,n)}$, in the a—x relations.

389   Since rigorous error propagation is not applicable to our experimental database (see Supplementary

390   Material 4), uncertainties on most of the compositional variables for the experimental samples have

391   been simply set to ± 0.01 apfu, a default value typically adopted in avP (Powell and Holland 2008).

392   Given the difficulty of quantifying realistic uncertainties on the spinel a–x model, which does not

393   account for cation ordering, uncertainties on x^{sp} [$Fe^{2+}/(Fe^{2+}+Mg)$] and f^{sp} [Fe^{3+}] have been set to 0.04

394   apfu, with the aim of accounting for the possible oversimplification of spinel a-x relations. This

395   simplified set of compositional uncertainties was then compared with the true uncertainties, derived

396   from partial error propagation, during trial calculations on the refined experimental database using

397   SCOlP equilibria. No significant difference was found in the results. In this test, we also noted that the

398   maximum variations of $\overline{P}$ between different uncertainties assumptions are on the order of $\sigma_{\overline{P}}$, as

399   suggested by Powell and Holland (2008).

400   For the natural samples, the mineral compositions used for thermobarometry are taken from

401   individual spot analyses of adjacent crystal rims, since adjacent rims are assumed to most closely

402   represent the equilibrium assemblage. The compositional errors are initially derived from counting

403   statistics of the electron microprobe (Supplementary Table 5). Given that such errors are small and

404   weakly correlated, partial error propagation is assumed to yield sufficiently realistic uncertainties for

405   most of the a–x model compositional variables. However, after applying the partial error, uncertainties

17

406   on compositional variables x(sp) and f(sp) (Supplementary Material 2) have been increased by a factor

407   of 4, consistent with the modifications adopted for the experimental samples described above.

408   By default in THERMOCALC, uncertainties on the interaction energies are set to $\pm$ 2 kJ mol^{-1} (Powell

409   and Holland 2008). For the a–x models used here, uncertainties on many interaction energies are not

410   well constrained and therefore we chose initially to retain this approximation during the assessment of

411   avP calculations on the experimental database. Once the final set of modified a–x models had been

412   selected, we noted that avP calculations produced low σ_{fit} ($<<$ 1.0) for many experimental runs and

413   natural samples, implying that the overall input uncertainties were in many cases excessive. We

414   therefore reduced the uncertainties on interaction energies to $\pm$ 1 kJ mol^{-1}, which increased to σ_{fit} values

415   generally closer to 1.0 (Supplementary Material 1 and Table 3) and decreased $\sigma_{\bar{P}}$ by about 0.2 kbar.

416   Such generalised uncertainties on interaction energies were adopted as they represent the best

417   compromise to simultaneously obtain low $\sigma_{\bar{P}}$ and successfully prediction of experimental pressures. In

418   fact, this might be a realistic estimate of the uncertainties on the most critical parameters, but many of

419   the less influential parameters are much less well known.

420   During avP calculations applied to experimental samples, the values of P_0 and T_0 were set to T_{exp}

421   and P_{exp} (we note that uncertainties in the measured pressure and temperature of the experimental runs

422   can be as high as $\pm$0.5 kbar and $\pm$20˚C). In the case of natural samples, P_0 was set to 4 kbar,

423   representing the middle of the range of crustal pressure. For both experimental and natural samples, the

424   window within which the avP algorithm should search for the P_r values was set to $P_0 \pm$ 20 kbar.

425   Methods for choosing T_0 for natural samples are discussed in a later section.

AvP calculations on the experimental database

427   In this section we report the results of avP calculations on the experimental database using the refined

428   thermodynamic models and the associated uncertainties adopted in this work.

18

429 **AvP output: $\overline{P}$, $\sigma_{\overline{P}}$ and σ_{fit}**

430 **Spinel + clinopyroxene + olivine + plagioclase equilibria (SCOlP).** The results of calculations using

431 SCOlP on the 62 experimental samples are good, as shown in Figure 5a (see also Supplementary

432 Material 1). 65% of the calculations passed the χ^2 test (i.e., $\sigma_{\text{fit}} < 1.49$), which indicates that the

433 experimental mineral compositions and the thermodynamic data, with their associated uncertainties,

434 can be safely combined in the averaging procedure. Slightly higher σ_{fit} values (no more than 20%

435 higher than the cut-off imposed by the χ^2 test) might still be considered acceptable, especially since $\sigma_{\overline{P}}$

436 is increased by a factor equal to σ_{fit} when the χ^2 test is failed. This would increase the proportion of

437 acceptable calculations to 82%. For the calculations that passed the χ^2 test, $\sigma_{\overline{P}}$ varies between 0.80 and

438 2.10 kbar, with a mean value of 1.24 kbar. Considering all the calculations, the experimental pressures

439 are predicted within $\sigma_{\overline{P}}$ for 67% of the samples, consistent with the expectation that the interval $\overline{P} \pm \sigma_{\overline{P}}$

440 will encompass the experimental pressure 68% of the time. The accuracy of avP can also be

441 demonstrated by calculating SEE for $\overline{P}$. For the selected experimental dataset the calculated $\overline{P}$ yields a

442 SEE of $\pm$ 1.37 kbar ($\pm$ 1.20 kbar considering only calculations with χ^2 test passed), which is small

443 relative to the typical values obtained by the existing geobarometers for gabbroic assemblages. For

444 example, the clinopyroxene-orthopyroxene barometer of Putirka (2008) (his eq. 39) has SEE = $\pm$ 2.8

445 kbar using his experimental database and SEE = $\pm$ 2.7 kbar using our filtered experimental database

446 (see Supplementary Material 1) in the P range 0.5–10 kbar.

447   No dependence of the pressure residuals ΔP ($\overline{P} - P_{\text{exp}}$) on P_{exp} (Fig. 5a) or T_{exp} (Fig. 6a) is observed,

448 suggesting that the P- and T-dependency of the adopted a–x relations is appropriate for the purpose of

449 avP calculations. Furthermore, the residuals are not dependent on the composition of plagioclase (An =

450 25–94 mol %), olivine (Fo = 61–95 mol %) or spinel ($Fe^{3+}/[Fe^{3+}+Al+Cr]$ = 0.00–0.90; Fig. 6b). For

451 clinopyroxene, the residuals do not appear to vary with composition, although a slight dependence of

452    $\sigma_{\overline{P}}$ with mg# might be inferred (Fig. 6c), given the apparent higher values of $\sigma_{\overline{P}}$ when mg# < 0.80. No

453   correlations or systematic deviations in ΔP are observed between hydrous and nominally-anhydrous

454   experiments (Supplementary Material 1). Overall, the application of avP to SCOlP with the adopted

455   thermodynamic model produces satisfactory results for a wide range of experimental compositions, and

456   can therefore be applied with confidence to natural mafic and ultramafic rocks that contain spinel,

457   clinopyroxene, olivine and plagioclase. More accurate $Fe^{3+}/\Sigma Fe$ estimations for clinopyroxene and

458   spinel would likely increase the accuracy of the calculated pressures. However, the good avP results

459   obtained in our calculations suggest that the errors related to Fe^{3+} calculated from stoichiometry do not

460   generally have a significant deleterious effect on $\overline{P}$.

461   **Clinopyroxene + olivine + plagioclase equilibria (COlP).** Fig. 5b shows the results of avP

462   calculations with COlP equilibria on the same experimental dataset used for SCOlP. Most of the

463   calculations passed the χ^2 test ($\sigma_{fit} < 1.73$) and $\sigma_{\overline{P}}$ varies between 0.93 kbar and 3.20 kbar. Results for

464   samples at $P_{exp} \geq 5$ kbar show a good agreement with the experimental pressures and low calculated

465   uncertainties (Fig. 5b). However, pressures are overall predicted within the uncertainties for a smaller

466   proportion of experiments (54%), which is linked to a systematic overestimation of ~ 1.5 kbar for

467   samples equilibrated at $P_{exp} < 5$ kbar. Comparable results were obtained on the entire dataset of 209

468   experiments containing COlP (Supplementary Material 6). We suspect that the source of the

469   overestimation at lower pressures could be an excess amount of Al^{IV} in clinopyroxene related to growth

470   rate (Mollo et al. 2010), which is expected to have a relatively larger effect where equilibrium values

471   for Al^{IV} are low, i.e., at low pressures. This issue does not significantly influence the accuracy of $\overline{P}$

472   when reactions involving spinel end-members are included in the independent set (i.e., SCOlP).

473   **AvP output: residuals and correlations**

20

474   In this section we examine the results of the least-squares minimization for the individual end-members

475   involved in the reactions and the correlation between the six SCOIP reactions. The low σ_{fit} values

476   obtained for most of the calculations on the experimental database indicate that, in general, the

477   calculated end-member activities and enthalpies do not have to be adjusted outside their uncertainties to

478   obtain a consistent value of P (i.e. $\overline{P}$) for the six reactions. In the avP diagnostics this is shown by the

479   low uncertainty-normalised residuals in log (activity) (e_i^*) and the enthalpy (H_i^*) for each end-member i

480   (see Supplementary Material 2). For calculations that passed the χ^2 test, $|e_i^*|$ is always <2.5 and $|H_i^*|$ is

481   always <1.0 for all end-members. No systematic outliers appear for the calculations on different

482   samples, with both e_i^* and H_i^* scattering randomly around zero. The only exception is for the end-

483   member acmite, which shows e_i^* varying between -0.1 and 2.5 and H_i^* between -0.2 and 1.4. Possibly,

484   such systematic positive residuals indicate a slight systematic overestimation of Fe^{3+} in clinopyroxene

485   as determined by stoichiometry.   For calculations that did not pass the χ^2 test no end-member is

486   identifiable that systematically shows high residuals (i.e., $|e_i^*| > 2.5$ and $|H_i^*| > 1.0$). The diagnostic h_i

487   (see Supplementary Material 2) shows that for most of the experimental samples no single end-member

488   has a prevailing influence on the calculated $\overline{P}$. The end-members that are most likely to be influential

489   are cats, cenh, sp, herc and jd. However, in a typical calculation such as that illustrated in the

490   Supplementary Material 2, if the uncertainty on $\ln a_i$ of any single end-member i is doubled, the value

491   of $\overline{P}$ changes by ≤ 0.2 kbar, except in the case of cats for which it is reduced by 0.4 kbar.

492   Supplementary Material 7 shows the correlation matrixes of the enthalpies of reactions (ΔH_r), $\ln K_r$ and

493   P_r, for the calculations on the experimental database. The matrix of ΔH_r values is the same in each

494   calculation. ΔH_r values for the reaction pairs r1-r4 (0.729), r2-r4 (0.746) and r3-r5 (0.741) are

495   particularly highly correlated due to their shared end-members. These reaction pairs also show

496   relatively highly correlated values of $\ln K_r$, but the magnitude of the correlations in $\ln K_r$, and

497   consequently in P_r, are strongly dependent on phase compositions. In a calculation for which P_{r3} and P_{r5}

21

498   have a correlation coefficient of 0.99, these two reactions amount to a single independent constraint on

499   how the end-member properties should be adjusted to attain a consistent $\overline{P}$. However, in calculations

500   involving other phase compositions these reactions show only weak to moderate correlation.

501   **Sensitivity of AvP to P_0 and T_0**

502   Calculations with avP require an initial estimate of pressure (P_0) and temperature (T_0) to be specified.

503   These are needed for the initial calculation of end-member enthalpies and activities. We performed a

504   test to investigate how different assumptions about P_0 and T_0 may influence the calculated SCOlP

505   equilibria and the subsequent results of avP. Multiple calculations with avP on the selected experiments

506   have been performed, firstly varying P_0 in the range 0–15 kbar (with $T_0 = T_{exp}$) and then varying T_0 in

507   the range 600–1400°C (with $P_0 = P_{exp}$). The first tests showed a negligible effect of P_0 on the calculated

508   pressure. For the sample ShR658 (P_{exp} = 2.0 kbar, T_{exp} = 1075 °C; Supplementary Material 1), for

509   example, a substantial difference of 15 kbar in P_0 produces a difference in the calculated $\overline{P}$ of 0.01 kbar

510   ($\overline{P}$ = 2.94 ± 1.62 kbar if P_0 = 0 kbar; $\overline{P}$ = 2.95 ± 1.62 kbar if P_0 = 15 kbar), with no difference in the

511   quality of the fit. Similar results have been observed for other experimental samples in the dataset.

512   On the other hand, different assumptions about T_0 variably affect the calculated $\overline{P}$. An example is

513   reported in Fig. 7, which shows the results for the same experiment ShR658. In this case, the

514   temperature dependence of $\overline{P}$, $d\overline{P}/dT_0$, corresponds to -0.012 kbar/°C. More generally the test on the

515   experimental dataset showed that $d\overline{P}/dT_0$ is always negative. Furthermore, the absolute value of the

516   dependence of $\overline{P}$ on T_0 is smaller for greater values of $\overline{P}$, with $d\overline{P}/dT_0$ varying from -0.016 to -0.002

517   kbar/°C (Fig. 8). This indicates that, for natural assemblages equilibrated at high pressures, even errors

518   related to crude temperature estimates (e.g., from geological/petrological inferences) will not

519   significantly increase the uncertainty on the calculated pressure (i.e., additional ± 0.4–0.6 kbar for

520   errors on T_0 on the order ± 150–200°C).

521   For assemblages equilibrated at relatively low pressures (<5kbar), uncertainties on T_0 on the order of

522   150–200˚C might increase the total pressure uncertainties by 1.5–2.5 kbar, which indicates the need of

523   reliable methods to estimate equilibration temperature when applying avP to natural samples. One such

524   a method is to carry out the avP procedure at multiple temperatures, and observe the variation in the

525   value of σ_{fit}. If the variation of σ_{fit} with T_0 follows a polynomial function of the type $\sigma_{fit} = a'T_0^2 + b'T_0$

526     $+ c'$ (where a', b' and c' are constants and a' > 0, b' < 0), and a minimum of σ_{fit} is clearly identifiable

527   (e.g., Fig. 7), then the value of T_0 that gives the minimum value of σ_{fit} can be considered to give better

528   estimates of T. Figure 7 shows a successful example of such a method, in which the estimated

529   temperature ($T\sigma_{fit}$; 1050˚C) is close to the measured experimental temperature, T_{exp} (1075˚C). We

530   applied such a method to the selected experimental dataset, firstly to evaluate the reliability of the

531   estimated temperatures and secondly to assess how the possible errors associated with these estimates

532   affect the calculated $\overline{P}$. For some experiments the variation of σ_{fit} with T_0 is such that a minimum in σ_{fit}

533   cannot be identified and therefore these experiments (n = 25) have been removed from the test dataset.

534   The results of the test are reported in Figure 9, which shows that $T\sigma_{fit}$ predicts the experimental

535   temperatures with a SEE of ± 93˚C (n = 37). Application of avP to the same experimental dataset,

536   adopting $T_0 = T\sigma_{fit}$ instead of $T_0 = T_{exp}$, still produces acceptable calculated pressures (cf. Figs. 9b and

537   d).

538   We note that $\sigma_{\overline{P}}$ also varies with T_0, and the minima in $\sigma_{\overline{P}}$ and σ_{fit} do not generally occur at the

539   same T_0. This suggests that temperature is not strongly constrained in the sample. We find empirically

540   that the optimal T_0 is usually better predicted by the minimum in σ_{fit}, even when σ_{fit} passes the χ^2 test

541   over a wide range of temperatures. The use of $T_{\sigma_{fit}}$ as a possible T estimate can be justified in that σ_{fit}

542   characterises the compatibility of the different independent reactions, and T_0 contributes to the

543   formulation of those reactions without being formally included in the covariance matrix summarised by

544     $\sigma_{\overline{P}}$.

23

545   In conclusion, P_0 does not have significant effects on the calculated $\overline{P}$ at any condition and therefore

546   we suggest the initial estimate to be always set to 4 kbar (i.e., mid-crustal values). On the other hand,

547   the effect of T_0 might be in some cases significant, but it can be easily evaluated for each sample by

548   running multiple avP calculations at different T_0. If no other thermometer can be applied that gives T

549   uncertainties < 90 ºC, then $T_0 = T_{\sigma_{\text{fit}}}$ can be used to produce the best estimate of P.

550   **Application to natural rocks**

551   Given the success of tests on the experimental dataset, we next applied the refined thermodynamic

552   models to estimating the pressure of formation of igneous rocks, choosing samples containing spinel,

553   clinopyroxene, olivine and plagioclase. We carefully selected two groups of mafic/ultramafic xenoliths

554   with texture, mineralogy and mineral chemistry suggesting good attainment of chemical equilibrium.

555   Compositions of minerals in these natural samples are reported in Fig. 2. The first group of xenoliths,

556   from the island of Dominica, Lesser Antilles, provides an example of the application of avP to gabbroic

557   rocks from a mid-upper island arc crust. The second group, which was described and analysed by

558   McGuire (1994) and McGuire and Mukasa (1997), is from the Wikieup volcanic field, Arizona, and

559   provides an example of gabbroic and ultramafic xenoliths from the lower continental crust. Unless

560   otherwise specified, the following discussion refers to calculations with SCOlP.

561   **Gabbroic xenoliths from Dominica, Lesser Antilles**

562   **Background, sample description and analyses.** The Lesser Antilles is an active volcanic arc resulting

563   from westwards subduction of the South American plate beneath the Caribbean plate (Macdonald et al.

564   2000). The volcanic products, which vary from basalts to andesites and dacites, host a large number of

565   plutonic xenoliths showing a variety of mineralogical compositions (Arculus and Wills 1980; Tollan et

566   al. 2012; Stamper et al. 2014b; Cooper et al. 2016). The ubiquity of these xenoliths provides an

567   exceptional opportunity to investigate the nature of the crust and the evolution of magmatic systems in

24

568   an island arc setting, but such an investigation requires precise estimates of the pressure of formation of

569   the xenoliths. Given that the estimated thickness of the crust in the Lesser Antilles varies between 25

570   and 35 km (cf., Boynton et al. 1979; Christeson et al. 2008; Kopp et al. 2011), the gabbroic xenoliths

571   are likely to have equilibrated at pressures between ~1 and ~8 kbar. Therefore, only geobarometric

572   estimates with low associated uncertainties (<2 kbar) can provide useful insight into the vertical

573   distribution of mafic lithologies in the crust.

574   Dominica, in the centre of the arc, is mainly composed of Pliocene to recent volcanic rocks (Lindsay

575   et al. 2005; Howe et al. 2015). Plutonic xenoliths, mostly consisting of gabbroic assemblages with or

576   without olivine, orthopyroxene and hornblende, have been found as clasts in young, reworked

577   sediments from the southern part of the island. For the purpose of testing the applicability of the avP

578   method, we selected three xenoliths containing the assemblage SCOlP, which have been collected from

579   marine deposits close to the village of Petite Savanne (southern Dominica), on the edge of the

580   Foundland volcanic centre. A schematic description of these samples, highlighting the main textural

581   and mineralogical features, is shown in Supplementary Material 8. Note that xenolith DC93 is

582   composed of two parts (a coarse-grained troctolite, DC93a, attached to a heterogranular Ol-

583   gabbronorite, DC93b).

584   Details of electron microprobe analyses and results are reported in the Supplementary Material 5.

585   Compositions of olivine, spinel, clinopyroxene and plagioclase (Fig. 2) are similar to those found in

586   other cumulate xenoliths from the Lesser Antilles (e.g., Tollan et al. 2012; Stamper et al. 2014b;

587   Cooper et al. 2016). Coexisting olivine and plagioclase show relatively low forsterite contents (68–73

588   mol% Fo) and high anorthite contents (87–93 mol% An) respectively; clinopyroxenes are augites

589   showing a limited range of mg# (78–82 %); spinels are titanomagnetites with TiO_2 contents of 7.6 to

590   9.2 wt%. Grain-to-grain and core-rim variations for olivine, spinel, pyroxenes and plagioclase are

591   small, suggestive of well-equilibrated assemblages. The largest compositional variations are observed

592   in samples DC91 and DC93b (e.g., $Al_2O_3^{cpx}$ = 1.9–3.7 wt% for DC91). Clinopyroxene in DC93b shows

593   a poikilitic texture with anhedral spinel inclusions and a slight patchy zoning mainly limited to Al^{IV}

594   (0.07–0.13 apfu) and Fe^{3+} (0.03–0.04 apfu). For the purpose of thermobarometry, only the

595   compositions of adjacent crystal rims have been used (Fig. 10).

596   **Average P calculations.** Mineral compositions reported in Supplementary Material 5 have been used

597   to calculate $\overline{P}$, adopting the thermodynamic models and calculation methods described above (see also

598   Supplementary Material 2 for the example of an avP calculation on sample DC90). T_0 has been

599   estimated by running a calculation every 10˚C in the range 700–1200˚C, and selecting the temperature

600   that produce the lowest σ_{fit} ($T\sigma_{fit}$) (see above and Fig. 7). Temperatures calculated with this method

601   (870–1000˚C) and results of avP calculations are reported in Table 3. All calculations produced low σ_{fit}

602   values (0.81–1.54) and $\sigma_{\overline{P}}$'s for each sample are low (0.91–1.55 kbar). The lowest $\sigma_{\overline{P}}$ is obtained for

603   the ol-gabbronorite DC90 ($\overline{P}$ = 3.58 ± 0.91 kbar), which is the sample with the smallest compositional

604   heterogeneities and best-equilibrated texture (e.g. ~120˚ grain boundaries). The cpx-amph-gabbronorite

605   DC91 contains also minor orthopyroxene, which allowed for application of cpx-opx thermometry

606   (Putirka 2008; Table 3). T estimated with this method is in agreement with $T\sigma_{fit}$ (896 vs 910 ˚C),

607   although the observed $K_D(Fe\text{-}Mg)^{cpx\text{-}opx}$ is below the range considered by Putirka (2008) to demonstrate

608   equilibrium (i.e., 0.79 vs. 1.09 ± 0.14). Pressure estimated for this sample (at $T_0 = T\sigma_{fit}$) is 1.94 ± 1.09

609   kbar. For all four Dominica samples, uncertainty-normalised residuals are low ($|e_i^*| < 1.5$, $|H_i^*| < 0.27$),

610   with acmite showing somewhat higher values (($|e_{acm}^*| < 2.1$, $|H_{acm}^*| < 0.87$), as observed for the

611   calculations on the experimental database. End-members cats, cenh, and jd show the highest, but still

612   acceptable, h_i values (h_{cats} = 0.26–0.30, h_{cenh} = 0.12–0.18, h_{jd} = 0.29–0.35). Calculations with COIP

613   produced comparable pressure estimates and uncertainties, although $\overline{P}$ is systematically higher (by ≤ 1

614   kbar, Table 3), as previously observed in tests on the experimental database at $P_{exp} < 5$ kbar.

26

615   The composite xenolith DC93 contains two assemblages (DC93a, DC93b; Supplementary Material

616   8 and Fig. 10) that show different textures and degrees of chemical and textural equilibrium despite

617   likely forming at the same pressure. Ol-gabbronorite DC93b show somewhat larger compositional

618   heterogeneities and lower Al^{IV} and Fe^{3+} in clinopyroxene compared to troctolite DC93a

619   (Supplementary Material 5), which is most likely related to a difference in bulk composition. This

620   provides an opportunity to test the effect of such heterogeneities on avP calculations with SCOlP.

621   Calculated pressures for samples DC93a and DC93b are in good agreement (2.67 ± 1.35 kbar vs, 2.81

622   ± 1.55 kbar), supporting the robustness of avP.

623   The geobarometric results obtained for these samples give an estimate of the pressures of magma

624   storage and crystallization in southern Dominica. Overall, the calculated pressures are in agreement

625   with the range inferred by observational and experimental studies on magmas and cumulate rocks from

626   the Lesser Antilles (i.e. mostly 1.0–5.0 kbar for gabbroic assemblages; c.f., Pichavant and Macdonald

627   2007; Stamper et al. 2014b; Melekhova et al. 2015; Cooper et al. 2016). Pressure calculated for the

628   cpx-amph-gabbronorite DC91 (1.94 ± 1.09 kbar) agree very well with the pressures of orthopyroxene

629   and plagioclase crystallization in lavas from southern Dominica (~2 kbar; Gurenko et al. 2006),

630   estimated using melt inclusion data and H_2O-CO_2 solubility models. Considering an average density

631   ($\bar{\rho}$) of the crust of 2800 kg/m^3, the calculated $\overline{P} \pm \sigma_{\overline{P}}$ for this cpx-amph-gabbronorite corresponds to a

632   depth of 7.1 ± 4.0 km, which agrees with the estimated hypocentres of deep volcanic earthquakes in the

633   nearby Plat Pays volcanic complex (2–6 km; Lindsay et al. 2003), thought to result from pressurization

634   of the magma reservoirs. Note that application of the cpx-opx geobarometer of Putirka (2008; his eq.

635   39) to the same sample DC91, which produces an estimated value of 1.6 kbar (as stated above, K_D[Fe-

636   Mg]$^{cpx\text{-}opx}$ < 0.95 potentially flags incomplete equilibration), is accompanied by a model uncertainty of

637   ± 2.8 kbar (Putirka 2008). This corresponds to an uncertainty of ± 10.2 km in the estimated depth of

638   formation.

639   Pressures estimated for ol-gabbronorite DC90 and troctolite DC93a correspond to depths of 13.0 ±

640   3.3 km and 9.7 ± 4.9 km respectively. Based on the seismic reflectors identified for the crust north of

641   Dominica (Kopp et al. 2011), such depths correspond to the middle-to-upper crust transition. Figure 11

642   shows how the thermobarometric results on all three xenoliths compare with the geophysical model of

643   Kopp *et al*. (2011). Note that among the existing geobarometers calibrated for basaltic compositions,

644   only the single-clinopyroxene formulations of Nimis (1995) and Putirka (2008) could be applied to

645   these assemblages[2]. Application of equation 32a of Putirka (2008) produces P = 9.4 ± 3.1 kbar for the

646   sample DC90 and P = 9.9 ± 3.1 kbar for the sample DC93a, which corresponds to depths of 34.2 ± 11.3

647   km and 36.0 ± 11.3 km, respectively, exceeding the crustal thickness in this area (27 km; Kopp et al.

648   2011). Overall, the successful application of avP to these samples suggest that future studies on a more

649   extensive xenolith suite from Dominica and elsewhere in the Lesser Antilles arc, combined with

650   petrological and geophysical observations, may help to constrain the lithological structure of the crust

651   with a precision not previously achievable.

652   **Mafic and ultramafic xenoliths from Wikieup, Arizona**

653   **Background and sample selection.** The Wikieup volcanic field is located in the Arizona Transition

654   Zone (south-western United States), between the Basin and Range Province (BRP), a region of thinned

655   continental crust (20–30 km), and the Colorado Plateau (CP), characterized by a thicker crust (40-50

656   km) that remained tectonically stable over the Phanerozoic (e.g., Bashir et al. 2011). The Wikieup

657   volcanics host a large number of mafic and ultramafic xenoliths thought to represent portions of the

658   underlying deep crust and upper mantle. Some of the xenoliths analysed by McGuire (1994) and later

659   by McGuire and Mukasa (1997) contain the assemblage SCOlP, making them suitable for application

660   of the avP method. Quantifying the thickness and nature of the crust in the Arizona Transition Zone is

661   important to interpret the tectonic and magmatic events that shaped the lithosphere of the southwestern

---

[2] Note that there are no tests for equilibrium (e.g., Putirka 2008) for clinopyroxene-only models.

28

662   US. Consequently a large number of geophysical investigations have been carried out in this area (e.g.,

663   Hauser et al. 1987; Parsons et al. 1992; Bashir et al. 2011 and reference therein), providing a context

664   for our thermobarometric results. McGuire (1994) presented such an approach using gabbroic

665   xenoliths, but due to the lack of reliable geobarometers for such assemblages, the estimated pressures

666   were poorly constrained.

667   Of the xenoliths described and analysed by McGuire (1994) and McGuire and Mukasa (1997) we

668   used four samples, from Tertiary alkaline olivine-basalts (Wilshire 1990) on the eastern flank of the

669   Hualuapai Mountains, that contain the assemblage SCOlP and for which mineral compositions are

670   available. Samples WK2-9 and WKa-49a are ol-gabbros; samples WK1-24 and WK1-63 are

671   plagioclase-peridotites. The latter show higher plagioclase and lower olivine contents with respect to

672   typical mantle peridotites, but show compositional and textural features that distinguish them from the

673   ol-gabbros (McGuire and Mukasa 1997). Both pl-peridotites and gabbros show allotriomorphic-

674   granular textures but pl-peridotites are also often foliated. Some textural evidence of early-stage

675   reactions between plagioclase and olivine grains has been reported (McGuire and Mukasa 1997), but

676   compositional heterogeneity is limited to some plagioclase grains that show slight normal zoning (<

677   2% An; McGuire and Mukasa 1997). Phase compositions are shown in Fig. 2 and detailed microprobe

678   analyses are reported in McGuire (1994) and McGuire and Mukasa (1997). Olivine shows a limited

679   variation in composition (Fo_{77-79}); spinel is Al-rich ($Al/[Al+Cr+Fe^{3+}]$ = 0.90–0.97) with low TiO_2

680   contents (0.11–0.45 wt%); clinopyroxenes are augites with Al_2O_3 contents varying from 6.91 to 7.49

681   wt%; and plagioclase varies between An_{52-53} (pl-peridotites) and An_{58-71} (ol-gabbros).

682   **AvP calculations.** All avP calculations passed the χ^2 test and the calculated uncertainties are notably

683   low (0.95–1.00 kbar; Table 3). Estimated pressures are similar within the uncertainties for all four

684   samples, but ol-gabbros shows some apparent lower values than pl-peridotites (Table 3). Similar

685   estimates are obtained using COlP, with no significant difference in the calculated uncertainties (Table

686   3), as previously observed at P > 5 kbar for our experimental test (cf., Figs. 5a and b). Note that ol-

687   gabbro WK2-9 and pl-peridotite WK1-63 also contain orthopyroxene, allowing $T\sigma_{fit}$ to be compared

688   with the results of cpx-opx thermometry (Putirka, 2008). Observed $K_D(Fe-Mg)^{cpx-opx}$ (0.94–0.95) are

689   within the range recommended for the application of such thermometer (Putirka, 2008). Temperatures

690   for the ol-gabbro WK2-9 agree fairly well (940˚C vs. 887˚C), while temperatures for the pl-peridotite

691   WK1-63 disagree by about 200˚C (Table 3). However, calculations for WK1-63 using T_0 estimated

692   from cpx-opx thermometry (T_0 = 953˚C instead of T_0 = 1150˚C) produce relatively small differences in

693   the calculated pressure (7.78 ± 0.86 kbar vs. 6.88 ± 0.97 kbar).

694   When calculated pressures for all four samples are converted to depths (Table 3), the resulting

695   values are consistent with those suggested by McGuire (1994) and McGuire and Mukasa (1997) based

696   on: i) the observation that many composite xenoliths show contact between gabbros and mantle

697   peridotites, suggesting an origin from the crust-mantle boundary (McGuire 1994) and ii) projection of

698   calculated temperatures onto the regional geotherm (100 mW/m^2; McGuire and Mukasa 1997). Our

699   calculations place more robust petrological constraints on the equilibration depths for comparison with

700   recent geophysical investigations (Bashir et al. 2011). Figure 12 shows that the calculated depths for

701   the ol-gabbros and pl-peridotites correspond closely to the lower crust levels in the integrated gravity

702   and seismic model of Bashir *et al.* (2011). Note that the upper-lower crust and crust-mantle boundaries

703   sketched in Fig. 12 should be viewed as transition zones and that the geophysical model has an

704   associated uncertainty, which that is not easily quantifiable (Bashir et al. 2011). The fact that both ol-

705   gabbros and pl-peridotites show comparable depths of formation is in agreement with a model of the

706   lower continental crust characterized by a network of dykes and sills of variably mafic lithologies

707   (McGuire 1994; Parsons et al. 1992), that can be related to the magmatic episodes that brought the

708   xenoliths to the surface. Further application of the avP method to a larger number of xenoliths,

709   combined with detailed modal analyses and integrated geophysical-petrological models, may help to

710   test this hypothesis.

Implications and final recommendations

712   Application of avP to experimental phase equilibria and well-equilibrated natural rocks has shown, for

713   the first time, that this method can be used to reliably estimate the pressure of formation for mafic and

714   ultramafic igneous rocks. The least squares minimization procedure in avP makes it possible to exploit

715   the power of internally-consistent thermodynamic datasets and mutually compatible a—x relations,

716   taking into account both uncertainties and correlations in end-member properties. It represents an

717   optimal method to deal with the inevitable inaccuracy of thermodynamic models and uncertainties on

718   mineral compositions. We demonstrated that calculations on SCOlP equilibria, using the models

719   refined in this work, yield i) good reproducibility of experimental pressures by avP (P is predicted,

720   within the calculated $\sigma_{\bar{P}}$, for 67% of the experimental database), ii) internal consistency of avP results

721   (i.e., χ^2 test passed) for the majority of phase equilibrium experiments and for the selected well-

722   equilibrated natural assemblages, and iii) low P uncertainties ($\sigma_{\bar{P}}$) as low as 0.9 kbar) for the same

723   assemblages. Pressure estimates with such low uncertainties can help to characterise the key

724   petrological processes and trace the vertical distribution of mafic and ultramafic lithologies in the upper

725   30–40 km of the lithosphere. Integration with geophysical data for the same areas affords potentially

726   powerful insights into crustal structure.

727   Modifications of the existing a–x models for clinopyroxene (Green et al. 2016) and spinel (Jennings

728   and Holland 2015) were necessary to avoid some observed pressure deviations resulting from initial

729   calculations with SCOlP. At present we believe that the thermodynamic models used in this work are

730   applicable to any gabbroic rock, pyroxenite or peridotite that contains olivine + clinopyroxene +

731   plagioclase in its equilibrium assemblage, regardless of geodynamic setting. This is supported by i) the

732   robustness of a multiple-reaction approach based on an internally consistent thermodynamic dataset

31

733   (Holland and Powell 2011) and ii) the successful tests on a database of phase equilibrium experiments

734   that cover a wide range of basaltic and peridotitic compositions (e.g., Figs. 5 and 6), both hydrated and

735   nominally-anhydrous. We believe the method can be applied also to volcanic rocks, for which,

736   however, the selection of equilibrium phase compositions might not be straightforward. Future test

737   cases, in which a detailed textural and chemical characterization of the phenocryst assemblages will be

738   coupled with the application of avP and its fit diagnostics, will help to test this hypothesis.

739   For equilibrated assemblages including spinel, calculations with SCOlP equilibria are always

740   preferred, since COlP slightly overestimate pressures (by 1–2 kbar) at upper-middle crust conditions (P

741   < 5 kbar). Calculations with SCOlP should be possible for a large number of mafic/ultramafic rocks, as

742   spinel is a ubiquitous phase in many natural gabbroic and basaltic rocks, and sometimes coexists with

743   plagioclase in shallow mantle peridotites/pyroxenites. Calculations with COlP, on the other hand, are

744   more likely to be needed for plagioclase-only peridotites/pyroxenites. Importantly, the latter typically

745   form at lower crust and uppermost mantle conditions (P > 5 kbar; e.g., Kelemen et al. 2007; Borghini et

746   al. 2011), corresponding to those pressures at which COlP calculations show low uncertainties and are

747   consistent with SCOlP based on tests on experimental (Fig. 5) and natural samples (Table 3).

748   The reliability of avP calculations on natural samples relies on the attainment of equilibrium in the

749   assemblage. If the assemblage shows slight intra- or inter-grain chemical heterogeneities, care should

750   be taken to select mineral compositions that are likely to be at equilibrium, as shown by the application

751   to the cumulate xenoliths from Dominica (Fig. 10). Secondly, when using our sets of independent

752   reactions (Fig. 4), temperature estimates for the sample need to be well constrained if the assemblage

753   equilibrated at P < 5 kbar. In order to estimate the true T of equilibration, it may be possible to use

754   existing thermometers, such as the cpx-opx thermometer of Putirka (2008) or the Ca-in-olivine

755   thermometer of Shejwalkar and Coogan (2013). Otherwise we suggest running avP calculations at

32

756 different temperature T_0, and select that which produces the lowest residuals (σ_{fit}) in the avP

757 minimization routine (Fig. 7).

758 Further work is planned to extend the avP approach to a wider range of phase assemblages. This will

759 entail testing and potential modification of thermodynamic models for orthopyroxene, amphibole and

760 ilmenite, which are also common constituents of mafic and ultramafic igneous rocks in various settings.

761 Using such a set of models, it will be possible to obtain mutually consistent pressure estimates for a

762 wide range of igneous rocks.

1064

1065 **Figure 1.** *P-T* conditions of phase equilibrium experiments in basaltic and peridotitic systems

1066 that contain at least olivine, clinopyroxene and plagioclase in their phase assemblages. Source

1067 references for this database are reported in Supplementary Material 1.

1068

1069 **Figure 2.** Composition of the mineral phases used for avP calculations on experimental and

1070 natural samples. (**a**) Pyroxene quadrilateral projection (Morimoto 1988). (**b**) Forsterite content in

1071 olivine plotted vs anorthite content in plagioclase. (**c**) Trivalent cation plot for spinels [Fe^{3+} =

1072 $Fe^{3+}/(Fe^{3+}+Al+Cr)$, $Al = Al/(Fe^{3+}+Al+Cr)$, $Cr = Cr/(Fe^{3+}+Al+Cr)$].

1073

1074 **Figure 3.** Variation of Al^{IV} in clinopyroxene with pressure in the experimental database. Note the

1075 wide range of Al^{IV} for the experiments at 0.001 kbar, which is larger than the variations for the

1076 entire dataset at higher pressures.

1077

1078 **Figure 4.** Independent set of reactions and avP results at $T_0 = 870$ ˚C for the spinel +

1079 clinopyroxene + olivine + plagioclase (SCOlP) assemblage in olivine-gabbronorite DC90

1080 (Dominica, Lesser Antilles). The reactions are linearised at $T_0 = 870$ ˚C and $P_0 = 4$ kbar. In the

1081 minimization procedure, avP makes minimal adjustments to the enthalpies and activities of end-

1082 members, given their covariance matrices, in order for the reactions to coincide at $\overline{P}$. Reactions

1083 derived from the initial input data, i.e. the dataset enthalpies and the activities at the measured

1084 compositions, are shown as solid curves. Reactions after minimization are shown as dashed curves.

1085 The box at the bottom shows the pressures initially obtained from each individual reaction with their

1086 associated uncertainties, at $T_0 = 870$ ˚C. For end-member abbreviations see Table 2. A detailed step-

1087 by-step demonstration of the same calculation is reported in the Supplementary Material 2.

1088

1089

47

1090   **Figure 5.** Results of avP calculations on the refined database of experiments containing the

1091   subset SCOlP in their run products. Calculations have been performed with either (**a**) SCOlP

1092   equilibria (i.e., 6 reactions) or (**b**) COlP equilibria (3 reactions), using the thermodynamic model

1093   refined in this work. Error bars are $\sigma_{\bar{P}}$ (see text). The labels on the x-axes are the experiment

1094   index numbers, ordered as in the Supplementary Material 1 (i.e., increasing P_{exp})

1095

1096   **Figure 6.** Residuals in calculated $\bar{P}$ relative to P_{exp}, for SCOlP equilibria, plotted vs. (**a**) T_{exp}, (**b**)

1097   spinel $Fe^{3+}/[Fe^{3+}+Al+Cr]$ and (**c**) clinopyroxene mg#. Dataset and symbols as in Fig. 5.

1098

1099   **Figure 7.** Results of multiple avP calculations at different temperatures T_0 for the experimental

1100   sample ShR658 (Husen et al. 2016). $P_0 = P_{exp}$ for all the calculations. The temperature

1101   dependence of the calculated pressure ($d\bar{P}/dT_0$) for this sample is indicated in the top box. $T\sigma_{fit}$

1102   is the value of T_0 that produces the avP result with the lowest σ_{fit} ($\bar{P}\sigma_{fit}$). Note, with reference to

1103   the uncertainty envelope (grey envelope in the top box), that outside the T range in which the χ^2

1104   test is passed, the uncertainty is multiplied by σ_{fit}.

1105

1106   **Figure 8.** Temperature dependence of avP ($d\bar{P}/dT_0$) plotted vs. calculated pressures (at $T_0 = T_{exp}$),

1107   for the selected experimental dataset used in this work. The higher the calculated value of $\bar{P}$, the

1108   less sensitive this value is to the choice of T_0.

1109

1110   **Figure 9.** Temperature estimates derived by minimising σ_{fit} ($T\sigma_{fit}$) for the experimental dataset

1111   and their effect on the calculated $\bar{P}$. (**a**) Comparison between $T\sigma_{fit}$ and the true temperature T_{exp}.

1112   (**b,c**) Test of $\bar{P} \pm \sigma_{\bar{P}}$ calculated using either (**b**) $T_0 = T\sigma_{fit}$ or (**c**) $T_0 = T_{exp}$. In (c), experiments

1113   shown in black are those for which $T\sigma_{fit}$ cannot be estimated, as no minimum in σ_{fit} as a function

1114   of T_0 can be identified. In all cases $P_0 = P_{exp}$. SEE: - Standard Error of Estimate; Pred: -

1115   percentage of calculations that predict P_{exp} within $\sigma_{\bar{P}}$.

1116

1117   **Figure 10.** Photomicrographs (plain polarised light) of the selected xenoliths from Dominica,

1118   with locations of the microprobe analyses used for avP calculations. Results of avP calculations

1119   with SCOlP equilibria are also reported in the boxes at the bottom-left corners.

1120

1121   **Figure 11.** Calculated depths for the three xenoliths from Dominica, Lesser Antilles, compared

1122   with the seismic model of Kopp et al. (2011). Depths calculated as in Table 3. Numbers in the

1123   figure refer to v_p velocities (km/s).

1124

1125   **Figure 12.** Calculated depths (as Table 3) for the ol-gabbro and pl-peridotite xenoliths from

1126   Wikieup, shown in comparison to the density profile across the Arizona Transition Zone (Bashir

1127   et al. 2011). BR – Basin and Range; CP – Colorado Plateau.

1137

1138 **Table 1.** Abbreviations used in this work

SCOlP	Spinel + Clinopyroxene + Olivine + Plagioclase, where 'spinel' may refer to either magnetite or Cr/Al-spinel.
COlP	Clinopyroxene + Olivine + Plagioclase
apfu	atoms per formula unit
mg#	$Mg/(Mg+Fe^{2+})$
NNO	nickel-nickel oxide buffer
P_{exp}, T_{exp}	measured pressure, temperature of the experiment
P_0, T_0	initial guesses of pressure and temperature
ΔG_r^o	Gibbs free energy difference in kJ for the reaction r among the pure end-members
ν_i	reaction coefficient for end-member i, at P, T
μ_i	total chemical potential for end-member i
μ_i^0	chemical potential of the pure end-member at P, T
R	gas constant (0.0083144 kJ/K·mole)
$W_{(m,n)}^j$	pairwise interaction energy representing non-ideal enthalpy of mixing between end-members m and n in phase j.
a_i	activity of end-member i
K_r	equilibrium constant for reaction r
ΔH_r	enthalpy change for reaction r, at P, T
ΔS_r	entropy change for reaction r, at P, T
ΔV_r	volume change for reaction r, at P, T
P_r	pressure at T_0 for reaction r
$\overline{P}$	average pressure (at T_0) calculated through the avP algorithm
$\sigma_{\overline{P}}$	calculated 1σ uncertainty for $\overline{P}$
σ_{fit}	diagnostic value that measures the appropriateness of the average, with σ_{fit}^2 distributed as χ^2.
e_i^*	uncertainty-normalized residuals in log (activity) for end-member i
H_i^*	uncertainty-normalized residuals in the enthalpy for end-member i
h_i	hat value, i.e., degree of influence of the end-member i on the least-square results
$T_{\sigma_{fit}}$	T_0 that produces the avP result with the minimum value of σ_{fit}
SEE	standard error of the estimate

1139

1140

1141

1142　**Table 2.** Solid solutions and compositional end-members used in this work. Columns SCOlP and
1143　COlP show which end-members are included in the avP calculations using the SCOlP and COlP
1144　equilibria, respectively. End-members are described in the Holland and Powell (2011) dataset, using
1145　the abbreviations shown, with the exception of cenh and cfs.
1146

Solid solution	End-member	Abbreviation	Formula	SCOlP	COlP
Olivine	forsterite	fo	Mg_2SiO_4	x	x
	fayalite	fa	Fe_2SiO_4	x	x
Spinel	spinel	sp	$MgAl_2O_4$	x	
	hercynite	herc	$FeAl_2O_4$	x	
	magnetite	mt	Fe_3O_4	x	
	picrochromite*	picr	$MgCr_2O_4$		
	ulvöspinel*	usp	Fe_2TiO_4		
Clinopyroxene	diopside	di	$CaMgSi_2O_6$	x	
	clinoenstatite	cenh	$Mg_2Si_2O_6$	x	x
	clinoferrosilite	cfs	$Fe_2Si_2O_6$	x	x
	jadeite	jd	$NaAlSi_2O_6$	x	x
	acmite	acm	$NaFeSi_2O_6$	x	
	Ca-tschermak	cats	$CaAl_2SiO_6$	x	x
Plagioclase	high-albite	abh	$NaAlSi_3O_8$	x	x
	anorthite	an	$CaAl_2Si_2O_8$	x	x
	sanidine*	san	$KAlSi_3O_8$		

1147　* end-members for which balanced reactions cannot be written. Note that these end-members are
1148　still considered in the calculations of the activities of the end-members involved in the reactions.
1149

1150	**Table 3.** Results of avP calculations for the xenoliths from Dominica and Wikieup. For all the
1151	calculations, $P_0 = 4.0$ kbar and $T_0 = T\sigma_{fit}$. Uncertainties on compositional variables have been
1152	propagated from analytical errors, with the corrections adopted in this work (see Supplementary
1153	Material 5). $T_{cpx\text{-}opx}$ refers to temperature calculated using eq. 37 in Putirka (2008). Depths of the
1154	xenoliths have been calculated from the estimated pressures, assuming an average density ($\bar{\rho}$) of
1155	the overlying crust of 2800 g/cm^3.

1156
