18   **ABSTRACT**

19   We performed melting experiments on Fe-O alloys up to 204 GPa and 3500 K in a diamond-

20   anvil cell (DAC) and determined the liquidus phase relations in the Fe-FeO system based on

21   textural and chemical characterizations of recovered samples. Liquid-liquid immiscibility was

22   observed up to 29 GPa. Oxygen concentration in eutectic liquid increased from >8 wt% O at 44

23   GPa to 13 wt% at 204 GPa, and is extrapolated to be about 15 wt% at the inner core boundary

24   (ICB) conditions. These results support O-rich liquid core, although oxygen cannot be a single

25   core light element. We estimated the range of possible liquid core compositions in Fe-O-Si-C-S

26   and found that the upper bounds for silicon and carbon concentrations are constrained by the

27   crystallization of dense inner core at the ICB.

28

29   **INTRODUCTION**

30   Oxygen is one of the likely candidates for light elements in the Earth's core (Hirose et al. 2013;

31   Morard et al. 2017). This hypothesis is supported by recent first-principles calculations showing

32   that both the density and sound velocity observed in the liquid core are compatible with the

33   presence of oxygen (Badro et al. 2014). The earlier calculations by Alfè et al. (2002) also stated

34   that oxygen is an important alloying element in the core; it is mostly partitioned into liquid iron

35   and can thus account for the large density contrast observed across the ICB.

36   Liquidus phase relations, in particular eutectic composition, provide another clue to constrain

37   the outer core composition. Even if oxygen is likely to be an abundant core light element, the liquid

38   core should not crystallize as FeO at the ICB; FeO is indeed lighter and thus cannot form the denser

39   solid inner core. Previous experiments clearly demonstrated that oxygen concentration in the Fe-

40   FeO eutectic liquid increases with increasing pressure (Ohtani et al. 1984; Ringwood and

41   Hibberson 1990; Seagle et al. 2008). Komabayashi (2014) developed a thermodynamic model that

42   predicts ~12 wt% O in the eutectic liquid composition at 330 GPa corresponding to the pressure

43   at the ICB. The most recent study by Morard et al. (2017) carried out melting experiments on Fe-

44   FeO to 102 GPa. They reported a sharp and large increase in oxygen concentration in the eutectic

45   liquid around 80 GPa, which contradicts earlier experimental results and the thermodynamic model

46   (Seagle et al. 2008; Komabayashi 2014).

47   Previous experiments showed immiscible Fe-rich metallic liquid and FeO-rich ionic liquid

48   below 25 GPa (Ringwood and Hibberson 1990; Tsuno et al. 2007). Frost et al. (2010) found a

49   small immiscible two-liquid region at 25 GPa and 2473 K, and the immiscibility is no longer

50   observed at 50 GPa (Seagle et al. 2008). The disappearance of the two-liquid region from the Fe-

51   FeO liquidus diagram should change the eutectic liquid composition as illustrated in Figure 1.

52   Here we report melting experiments on Fe-O alloys up to pressures of 204 GPa, which extends

53   the pressure range examined in earlier studies by a factor 2. On the basis of the eutectic liquid

54   composition determined in the core pressure range, we discuss the presence of oxygen and other

55   light elements in the outer core.

56

57   **EXPERIMENTAL METHODS**

58   High-pressure and -temperature (*P-T*) conditions were generated in a laser-heated DAC using

59   diamonds with culet size of 120, 150, or 300 μm (Table 1). We employed homogeneous Fe-

60   4.1wt%O and Fe-13.0wt%O starting materials, prepared by magnetron sputtering of Fe in a

61   inductively coupled RF (radio-frequency) reactive oxygen-rich argon plasma (Morard et al. 2017).

62   A sample flake was loaded with an Al_2O_3 pressure medium, into a 40–140 μm hole at the center

63   of a pre-indented rhenium gasket. After loading the sample, the whole DAC was dried in a vacuum

64   oven at 423 K for at least 12 hrs to eliminate moisture from the sample. It was then compressed in

65   an argon atmosphere.

66   At each pressure of interest, we heated the sample from both sides with a couple of 100 W

67   single-mode Yb fiber lasers (YLR-100, IPG Photonics) with flat-top beam-shaping optics. A

68   visible laser-heated spot was approximately 20 μm in diameter. The heating duration was limited

69   to less than 3 sec, in order to avoid temperature fluctuation that leads to a complex melting texture.

70   It is long enough for oxygen to diffuse over an entire melt pocket (Helffrich 2014) (Figs. 2a, b),

71   which assures chemical equilibrium between liquid and solid since melting/crystallization occurs

72   almost instantaneously. Indeed, the time-series experiments performed by Mori et al. (2017)

73   demonstrated that the compositions of coexisting liquid and solid in the Fe-S system did not change

74   after 1 sec in a DAC. Note that the diffusivity of oxygen is slightly higher than that of sulfur in

75   liquid Fe (Helffrich 2014). The temperature profile was obtained using a spectro-radiometric

76   method (Mori et al. 2017) (Fig. 2c). Following Mori et al. (2017) and Tateno et al. (2018), we

77   determined the temperature at the liquid/solid boundary by combining the temperature profile with

78   a sample cross section. Pressure was measured at 300 K after heating based on a Raman shift of

79   diamond (anvil) (Akahama and Kawamura 2004) and then corrected for thermal pressure based

80   on Andrault et al. (1998). We considered 60% of theoretical thermal pressure for purely isochoric

81   heating $\Delta P = \alpha K_\mathrm{T} \times (T - 300)$, $\alpha K_\mathrm{T} = 4$ MPa/K below 100 GPa, and adopted 90% of that with

82    $\alpha K_\mathrm{T} = 9$ MPa/K for runs at higher pressures (Hirose et al. 2017). These estimates differ from the

83   empirical one (5% pressure increase per temperature increase for every 1000 K) (Fiquet et al.

84   2010) by less than 7 GPa in all runs. The uncertainties in both P and T should therefore be less

85   than ±5−10 % (Table 1).

86   Textural and chemical characterizations were carried out on recovered DAC samples. A cross

87   section of the laser-heated portion of a sample was obtained parallel to the compression axis by

88   milling with a focused Ga ion beam (FIB, *FEI Versa*^{TM} *3D DualBeam*^{TM}). It was then examined

89   by a field-emission (FE)-type scanning electron microscope (SEM) and energy dispersive X-ray

90   spectrometry (EDS) for elemental mapping (Fig. 2a). We also used an FE-type electron probe

91   micro-analyzer (FE-EPMA, JEOL JXA-8530F) with wavelength dispersive spectrometry (WDS)

92   for quantitative chemical analyses; an accelerating voltage of 12 kV, a current of 15 nA, and the

93   X-ray counting time of 20s/10s for peak/background. Fe, Fe₃C, and corundum were used as

4

94   standards. LDE1 (O), LIF (Fe), LDE2H (C), and TAP (Al) were analyzing crystals. The FE-EPMA

95   analyses of quenched liquid iron sometimes included a small amount of Al, which is likely a signal

96   from the surrounding pressure medium or Al_2O_3 grains that mechanically intruded into the liquid

97   during the experiment (Figs. 2a, b). Al was therefore subtracted as Al_2O_3 from raw data. Carbon

98   was detected not only in the quenched liquid, but also inside the rhenium gasket; the latter could

99   be due to contamination during FIB processing or FE-EPMA analysis. Thus, we subtracted 0.2–

100   0.4 wt% C from the raw analyses of liquids, which was found on the rhenium gasket in the same

101   cross section (or in an unheated portion of a sample when the gasket was not included). The liquids

102   should have included the remaining 0.8–3.5 wt% C (Table 1).

103

104   **RESULTS**

105   We performed eight separate runs in a pressure range from 23 to 204 GPa (Table 1). In sample

106   cross sections, except for runs performed below 44 GPa, we found a chemically homogeneous area

107   with non-stoichiometric Fe-O composition at the center of a laser-heated area (Figs. 2a, b), which

108   likely represents a quenched liquid pool. There are layers of single-phase Fe or FeO (or both) next

109   to the liquid, which indicates which side of the eutectic the liquid was. A subsolidus part is found

110   outside such a liquidus phase layer.

111   In run #1 performed at 23 GPa and 2760 K, two large liquid pools were observed (Fig. 2d);

112   each one exhibits heterogeneous textures, similar to the ones reported in previous multi-anvil

113   experiments (e.g., Ringwood and Hibberson 1990; Tsuno et al. 2007). The two-liquid

114   immiscibility was also found in run #2 at 29 GPa, but not at pressures above 44 GPa in this study.

115   In runs #3–#6, the composition of a liquid represents the lower and upper bounds for oxygen

116   concentration in the eutectic liquid when coexisting with Fe and FeO, respectively (Table 1, Fig.

5

117   3). In runs #4 and #6, both Fe and FeO layers were found. As commonly observed in both multi-

118   anvil (e.g., Hirose and Fei 2002) and DAC experiments (e.g., Mori et al. 2017), a temperature

119   gradient in a sample induced phase segregation of each phase; in the present case, the layers of

120   liquid, FeO, and Fe were formed separately. Nevertheless, we estimate the difference in

121   temperature between the liquid/FeO boundary and the FeO/Fe boundary to be less than 50–60 K

122   considering the temperature gradient (Fig. 2c) (note that the FeO layer was about 1 μm wide as

123   shown in Fig. 2a). Since 50–60 K is less than the uncertainty in the present experimental

124   temperature determination, we considered that liquid, FeO, and Fe coexisted practically at the

125   same temperature. The liquid composition may therefore be the eutectic liquid when both Fe and

126   FeO layers were observed. The liquids obtained in runs #7 and #8 included remarkably less oxygen

127   than in the other runs; alternatively, they were enriched in carbon (Table 1). Except for these two

128   runs, the carbon amount was limited to ~1 wt%, with probably a limited effect on the Fe-FeO

129   diagram.

130   The experiments with limited carbon contamination show a change in the Fe-FeO eutectic

131   liquid composition with increasing pressure (Fig. 3). Above 44±4 GPa, the eutectic liquid includes

132   >8 wt% O, which is a remarkably high amount compared to that found in previous multi-anvil

133   experiments below 16 GPa (Ringwood and Hibberson 1990; Tsuno et al. 2007), where liquid-

134   liquid immiscibility is observed. The oxygen concentration increases to about 13 wt% at the

135   maximum pressure of 204±20 GPa explored here.

136   Since the composition of liquid obtained in the present study is close (or identical) to the

137   eutectic liquid composition at each pressure, the liquidus temperature determined as temperature

138   at the liquid/solid boundary should be close to (or represent) the eutectic temperature. Note that

139   the compositions of the present Fe-O-(C) liquids with limited carbon contamination do not

140   represent the Fe-O-C ternary eutectic compositions. Indeed iron carbides did not crystallize;

141   therefore their liquidus temperatures give the upper bounds for the ternary eutectic temperatures.

142   All data are in good agreement with the Fe-O eutectic melting curve reported by Morard et al.

143   (2017) on the basis of X-ray diffraction (XRD) observations (Fig. 4).

144

145   **DISCUSSION**

146   The present results show that the eutectic liquid composition in the Fe-FeO binary evolves

147   from Fe + >8 wt% O at 44±4 GPa to +13 wt% O at 204±20 GPa (Fig. 3). This observation is in

148   reasonable agreement with the previous DAC experiments by Seagle et al. (2008) based on the

149   disappearance of Fe or FeO from the XRD pattern, and with the thermodynamic model proposed

150   by Komabayashi (2014) considering a non-ideal mixing based on Frost et al. (2010). Extrapolation

151   of our data to 330 GPa suggests that the Fe-FeO eutectic liquid contains about 15 wt% O at the

152   ICB.

153   We observed the liquid immiscibility to 29±3 GPa and 2900±290 K, while Frost et al. (2010)

154   found a narrow Fe-FeO immiscible two-liquids region at 25 GPa and 2473 K. These two conditions

155   are similar when considering errors in P and T for both the experiments. In addition, since the

156   textures of quenched immiscible liquids are quite heterogeneous (see Fig. 9 in Frost et al. 2010

157   and Fig. 2d in this study), a precise determination of their chemical compositions is difficult.

158   Indeed, the compositions of the immiscible two liquids reported by Frost and others include large

159   uncertainties, suggesting that the immiscible two-liquids region may exist to P-T conditions higher

160   than 25 GPa at 2473 K to a certain extent.

161   The vanishing of the liquid immiscibility changes the Fe-FeO liquidus curves. According to

162   previous experiments (Ohtani et al. 1984; Ringwood and Hibberson 1990), the Fe-FeO eutectic

7

163   liquid includes minor amounts of oxygen at low pressures (~2 wt% at 16 GPa). The immiscible

164   two-liquids region is found around Fe+11wt%O to >25 GPa at 2473 K according to Frost et al.

165   (2010). Using the Fe-13.0wt%O starting material, we observed two immiscible liquids at 23 and

166   29 GPa (Fig. 2c). A single liquid was formed at 44 GPa, suggesting the disappearance of the

167   immiscible two-liquids region from the phase diagram. As illustrated in Fig. 1, a reduction in the

168   immiscible two-liquids region with increasing pressure causes the Fe-FeO eutectic point to shift

169   to a more O-rich region. It explains the high (>8 wt%) oxygen concentration in the eutectic liquid

170   at 44±4 GPa (Fig. 3).

171   The closure of immiscible two-liquids region also indicates that mixing between liquids Fe and

172   FeO is non-ideal at low pressures and becomes closer to ideal above 44 GPa. It is supported by the

173   eutectic melting curve shown in Fig. 4 that is in broad agreement with the thermodynamic

174   prediction by Komabayashi (2014) considering the ideal mixing. Furthermore, the pressure–

175   eutectic liquid composition relation observed in the present experiments is consistent with the

176   behavior shown by the non-ideal mixing model below ~50 GPa, while it could be explained by the

177   ideal solution model at higher pressures (Komabayashi 2014) (Fig. 3). The ideal solution model

178   by Komabayashi shows the lower oxygen concentration in the Fe-FeO eutectic liquid than the

179   present experimental results at >50 GPa, but his thermodynamic prediction depends on the

180   uncertain melting temperature of FeO, which can be much lower than he assumed.

181   While these results suggest that the oxygen content in the eutectic liquid increases with

182   increasing pressure to ~40 GPa, Morard et al. (2017) demonstrated it rises sharply around 80 GPa

183   (Fig. 3). The liquid coexisting with both Fe and FeO at 39 GPa in run #7 was contaminated by 3.1

184   wt% C and included only 0.4 wt% O, much less than that in the Fe-FeO eutectic liquid at equivalent

185   pressure. It is possible that the incorporation of carbon expands the immiscible two-liquid region

186 to higher pressures, which could explain the difference between these two studies. Morard et al.

187 (2017) estimated 0.8–2.7 wt% C with ±1.0 wt% uncertainty for liquids obtained below 80 GPa,

188 using Rietveld analyses of XRD patterns to find the amount of iron carbide formed in a quenched

189 liquid portion (after moderate re-heating after melting experiments). Since solid Fe can include 1

190 to 2 wt% C below 100 GPa (Walker et al. 2013; Fei and Brosh 2014), such estimates may be

191 underestimated. The observed low O content may be more relevant to the ternary Fe-O-C system

192 than for the binary Fe-FeO system.

193

194   **IMPLICATIONS**

195   In order to form the dense inner core, the liquid core should crystallize Fe that is depleted in

196 light elements compared to the outer core liquid. It was once suggested that the inner core is

197 composed mainly of Fe_7C_3 (Chen et al. 2014; Prescher et al. 2015), but recent calculations

198 demonstrated that the density of Fe_7C_3 is too small for the inner core (Li et al. 2016). The present

199 experiments demonstrate that oxygen concentration in the Fe-FeO eutectic liquid increases (in

200 other words, the liquidus field of Fe expands) with increasing pressure (Fig. 3). It contrasts the

201 other binary iron alloy systems. The amounts of silicon, carbon, and sulfur in corresponding Fe-Si

202 (Ozawa et al. 2016), Fe-C (Lord et al. 2009; Mashino et al. 2019), and Fe-S binary eutectic liquids

203 (Kamada et al. 2012; Mori et al. 2017) decrease at higher pressures. At 330 GPa, these amounts

204 are less than those required to explain the outer core density deficit when assuming a single light

205 element. It indicates that none of silicon, carbon, and sulfur can be a predominant light component

206 in the core.

207   The present experiments allow us to determine the Fe-FeO eutectic liquid composition to 204

208 GPa, which is a much higher pressure compared to earlier experiments (Seagle et al. 2008; Morard

209   et al. 2017). Our extrapolation to 330 GPa indicates ~15 wt% O in the eutectic liquid at the ICB

210   conditions. If oxygen is assumed to be the sole light element in the core, the calculations by Badro

211   et al. (2014) argued that 5.4 wt% O is required to account for both the density and bulk sound

212   velocity in the outer core. If this amount (Fe + 5.4 wt% O) is retained, such a system should sit on

213   the Fe-rich side of the eutectic and thus crystallize solid Fe at the ICB, which is consistent with a

214   dense inner core. However, oxygen is hardly soluble in solid Fe (<0.1 wt% at ICB conditions - see

215   Alfè et al. 2002; Ozawa et al. 2010). And the inner core is less dense than pure iron to some extent

216   (Antonangeli and Ohtani, 2015), thus suggesting that oxygen cannot be the sole light element in

217   the core.

218   Even if oxygen is not a predominant light element, the core should include (or should have

219   included) a certain amount of oxygen (Hirose et al. 2017), according to recent high-temperature

220   core formation models (e.g., Siebert et al. 2013). The present estimate of the Fe-FeO eutectic liquid

221   composition at 330 GPa is thus important for modeling the compositional evolution of the Earth's

222   core and for constraining the present-day core composition from the phase diagrams of iron alloys.

223   Recently Tateno et al. (2018) examined the liquidus phase relations in the Fe-Si-S ternary system

224   and found that the liquidus field of solid Fe is approximated by a tie-line connecting the two

225   eutectic points in the Fe-Si and Fe-S binary systems. If this is also true in Fe alloy systems

226   containing more light elements, we can estimate the liquidus field of solid Fe in Fe-O-Si-C-S at

227   the ICB, considering each binary eutectic liquid composition that has been already reported in the

228   literature: 15 wt% O in Fe-O (this study), 1.5 wt% Si in Fe-Si (Ozawa et al. 2016), 3 wt% C in Fe-

229   C (Mashino et al. 2019), and 5 wt% S in Fe-S (Mori et al. 2017).

230   The present-day outer core composition should be within the liquidus field of solid Fe at 330

231   GPa. It provides an additional constraint to narrow down the possible range for the outer core

232 composition (Fig. 5). The first-principles calculations by Badro et al. (2014) showed the range of

233 liquid Fe-O-Si-C-S compositions that explain both the density and sound velocity of the outer core.

234 That range is reduced when we consider such additional conditions required to form a dense inner

235 core. While Badro and others suggested that the silicon content could be as high as 4.5 wt%, the

236 amount of silicon in the possible liquid core composition is found to be small, and constrained by

237 the Fe-Si eutectic liquid composition. The estimate of sulfur concentration is similar. The minor

238 silicon content in the present-day outer core is consistent with the limited Si+O solubility in molten

239 iron under the core *P-T* conditions (Hirose et al. 2017). In addition, Badro et al. (2014)

240 demonstrated that the carbon content can be as high as 3.9 wt%, but our new constraint limits it to

241 less than 2.5 wt%.

333

334   **Figure captions**

335   **FIGURE 1.** Schematic illustration of the change in liquidus curve and eutectic point with
336   changing interaction energy in liquid after Tanaka and Nagasaka (2006).
337

338   **FIGURE 2.** Sample cross sections and temperature profile. **(a)** X-ray maps combining oxygen
339   (red) and aluminum (cyan) for a sample recovered from run #6 performed at 204 GPa and 3500 K.
340   Back-scattered electron image shows the liquid/solid boundary. **(b, c)** SEM image and the
341   corresponding temperature profile for run #5 at 132 GPa. The boundary between quenched liquid
342   and solid Fe is found on the basis of the difference in microtexture and the presence of Al_2O_3 grains
343   (black) that mechanically intruded from surroundings into a liquid. The temperature at the liquid-
344   solid boundary is estimated to be 3050 K, considering that the boundary was isothermal (the same
345   temperature for both sides). **(d)** The SEM image from run #1 showing immiscible two liquids at
346   23 GPa.
347

348   **FIGURE 3.** Oxygen concentration in liquid (red symbols). Normal and reverse triangles
349   indicate liquids coexisting with either one of solid Fe or FeO, respectively, giving the lower and
350   upper bounds for eutectic liquid composition. Diamonds show liquids coexisting with both Fe and
351   FeO that may represent the eutectic liquids. Closed circles are carbon-contaminated samples (>3
352   wt% C). Black diamonds represent eutectic compositions at 3 GPa (Ohtani et al. 1984) and 16 GPa
353   (Ringwood and Hibberson 1990). Red, blue, and black curves show the change in the Fe-FeO
354   eutectic liquid composition from this study (only with ~1 wt% carbon contamination), Morard et
355   al. (2017), and Seagle et al. (2008), respectively. Green and cyan curves are the thermodynamic
356   models assuming non-ideal and ideal solutions, respectively, by Komabayashi (2014).
357

358   **FIGURE 4.** Fe-FeO eutectic melting curve. Diamonds represent eutectic temperature obtained
359   at 3 GPa (Ohtani et al. 1984), 16 GPa (Ringwood and Hibberson 1990), and 48 and 204 GPa (this
360   study). Reverse triangles indicate the upper bounds for the eutectic temperature. Red and black
361   lines are the Fe-FeO eutectic melting curves obtained in this study and by Morard et al. (2017),
362   respectively. Small circles and squares are the previous experimental data by Seagle et al. (2008)
363   and Morard et al. (2017), respectively, showing the upper (filled) and lower bounds (open symbols)
364   for eutectic temperatures.
365

366   **FIGURE 5.** The range of possible Fe-O-Si-C-S liquid core compositions that crystallize solid
367   Fe at the ICB and account for the density and velocity of the outer core (Badro et al. 2014).

TABLE 1. Experimental conditions and results

Run #	Starting material	P (GPa) at 300 K	P (GPa)	T (K)	O (wt%) in liquid	C (wt%) in liquid	Coexisting solid phase
#1	Fe-13.0wt%O	17	23(2)	2760(280)	two liquids		none
#2	Fe-13.0wt%O	23	29(3)	2900(290)	two liquids		FeO
#3	Fe-13.0wt%O	38	44(4)	2860(140)	8.8(4)	1.3(1)	FeO
#4	Fe-13.0wt%O	43	48(5)	2580(130)	10.3(6)	1.4(1)	Fe + FeO
#5	Fe-4.1wt%O	110	132(13)	3050(150)	9.8(1)	0.8(0)	Fe
#6	Fe-13.0wt%O	178	204(20)	3500(350)	13.3(0)	1.1(0)	Fe + FeO
#7	Fe-4.1wt%O	34	39(4)	2260(110)	0.4(0)	3.1(1)	Fe + FeO
#8	Fe-4.1wt%O	74	79(8)	2310(120)	1.0(0)	3.5(1)	FeO
