17　**ABSTRACT**

18

19　　The thermoelastic behavior of a crystal of Fe-rich holmquistite with crystal-chemical

20　formula $^A(K_{0.01}Na_{0.01})^B(Li_{1.88}Mg_{0.10}Na_{0.02})^C(Mg_{1.68}Fe^{2+}_{1.42}Mn^{2+}_{0.02}Al_{1.88})^TSi_{8.00}O_{22}{}^W[(OH)_{1.97}F_{0.03}]$

21　was studied by single-crystal X-ray diffraction to 1023 K, where isothermal annealing in air for 160

1

22   hours yielded the loss of 0.85 H *apfu* coupled with oxidation of ^{M1}Fe. A complex pattern of cations

23   exchanges was deciphered by comparing structure refinements done before and after annealing. Li

24   migration from the *M*4 to the *M*3 site is responsible for non-linearity of the *c* parameter around 600

25   K during the first annealing. Cooling of the partially deprotonated crystal to R*T* showed

26   discontinuities in trends of the *b* and *c* parameters around 820-800 K, which cannot be ascribed to a

27   phase transition and must be explained by a rearrangement of the structural units affecting the

28   geometry of the *M*4 polyhedron. Such discontinuities have never been observed in amphiboles

29   before and must be related to dimensional constraints deriving from the peculiar composition of this

30   amphibole, which contains the smallest possible homovalent constituents, i.e., ^{B}Li, ^{C}Al and ^{T}Si. The

31   calculated thermoelastic parameters are: Fe-rich holmquistite: $\alpha_a = 1.36(2) \times 10^{-5}$; $\alpha_b = 0.55(1) \times 10^{-5}$;

32    $\alpha_c = 1.5(1) \times 10^{-5} - 6.7(9) \times 10^{-9}$; $\alpha_V = 3.5(3) \times 10^{-5} - 0.8(3) \times 10^{-8}$ (polynomial); $2.58(6) \times 10^{-5}$ (linear);

33   partially deprotonated Fe-rich holmquistite: $\alpha_a = 1.324(9) \times 10^{-5}$ (R*T*-1023 K); $\alpha_b = 0.60(1) \times 10^{-5}$

34   (R*T*-773 K); $\alpha_c = 0.68(2) \times 10^{-5}$ (R*T*-773 K); $\alpha_V = 2.59(2) \times 10^{-5}$ (R*T*-773 K). Fe-rich holmquistite is

35   much stiffer than all the previously studied orthorhombic *Pnma* and *Pnmn* amphiboles. The results

36   of this work allow progress towards a general model able that will explain how the amphibole

37   structure reacts to non-ambient conditions, and allows the release of water in diverse geological

38   situations.

39   **Keywords** Amphibole - Holmquistite - H*T* behavior - Thermoelasticity - Deprotonation -

40   Structure refinement

INTRODUCTION

42   Hydrous minerals with topologically complex structure and crystal-chemistry, such as

43   amphibole, mica, serpentine, tourmaline, have a complex behavior under increasing *T* and *P*. The

44   most relevant phenomena observed are expansion of the unit cell (often anisotropic), cation

45   disordering among sites with similar or different coordination, phase transitions and deprotonation

46   coupled with iron oxidation. All these processes significantly affect cation order, molar volume and

47   thermoelasticity in the studied phase. The reasons why and how deprotonation occurs is crucial to

48   model the release of water in some geological setting, such as during subduction or degassing

49   during ascent of magma in volcanic conduits.

50   Crystallographic studies concerning the evolution of the structure with *T* have been done so

51   far for amphiboles (after the review by Welch et al. 2007, see: Della Ventura et al. 2015, 2018a,b;

52   Oberti et al. 2009, 2011, 2016, 2018; Welch et al. 2011a,b; Zema et al. 2012) and micas (Ventruti et

53   al. 2008; Zema et al. 2010). Studies of the oxidation/deprotonation process based upon vibrational

54   spectroscopic evidences are also available for tourmalines (Fuchs et al. 2002; Pieczka and Kraczka

55   2004; Bačik et al. 2011; Filip et al. 2012; Bosi et al. 2016a,b) but do not provide information on

56   thermal expansivity. For serpentine, the loss of water has been monitored by TEM and

57   spectroscopic techniques (Gualtieri et al. 2012; Trittschack and Grobéty 2012, 2013).

58   Amphiboles are an important family of rock-forming minerals with a complex crystal-

59   chemistry. However, their compositional diversity gives them potential as sensitive monitors of

60   petrological processes; therefore, H*T* studies of amphiboles under controlled conditions are being

61   systematically done to confirm our present knowledge on cation ordering and exchange vectors

62   (which is mostly derived from crystal-chemical and petrological observations on many

63   compositions from different localities and geological environments) and to provide key information

64   for petrogenetic studies. Indeed, H*T* studies of amphiboles can provide precious information on

65   phase stability, molar volumes and crystal-chemical markers to be used in thermodynamic

66   modelling in upper-mantle geological contexts, as well as on the conditions of hydrogen release and

67   thus on the hydrogen/water budget in the Earth mantle. This last issue is becoming more and more

68   important, because it is not only related to plate tectonics but also to Earth's climate and habitability

69   (cf. for instance Yang et al. (2016) and references therein).

70   We have already examined the high-temperature and high-pressure behavior of two

71   compositions of the orthorhombic magnesium-iron- manganese amphibole subgroup by single-

72   crystal X-ray diffraction (SC-XRD): anthophyllite (ideally $^A\square^BMg_2{}^CMg_5{}^TSi_8O_{22}{}^W(OH)_2$; Welch et

3

73   al. 2011a,b) and gedrite (ideally $^{A}Na^{B}Mg_2{}^{C}(Mg_4Al)^{T}(Si_6Al_2)O_{22}{}^{W}(OH)_2$ but always occurring with

74   significant ^{A}Na and ^{C}Fe contents; Zema et al. 2012; Nestola et al. 2012). For proto-ferro-suenoite

75   (ideally $^{A}\square^{B}Mn^{2+}{}_2{}^{C}Mg_5{}^{T}Si_8O_{22}{}^{W}(OH)_2$ but occurring with a different symmetry, i.e. *Pnmn*), only

76   RT (Sueno et al. 2002) and HP data (Zanazzi et al. 2010) are available. Note that in the present

77   scheme for amphibole nomenclature and classification (Hawthorne et al. 2012) A, B, C and T refers

78   to the cations occurring at the *A* (*A, Am, A*2), *M*4, *M*1-3,*T*1-2 sites, respectively, and W refers to

79   anions occurring at the O3 site (cf. Figure 1 for site identification). For monoclinic amphiboles, the

80   use of parentheses, such as in *M*(4), is required.

81   We now report on the HT behavior of the third composition of reference for orthorhombic

82   *Pnma* amphiboles, holmquistite (ideally $^{A}\square^{B}Li_2{}^{C}(Mg_3Al_2)^{T}Si_8O_{22}{}^{W}(OH)_2$). Holmquistite is unusual

83   among amphiboles in that (i) the *A* site is empty (and hence more compressible and less

84   expansible); (ii) the two independent double-chains of tetrahedra are occupied by the smallest

85   possible T cation (Si), and (iii) they have to match with a strip built by three independent octahedra

86   (*M*1, *M*2 and *M*3), one of which (*M*2) is almost fully occupied by the smallest possible trivalent C

87   cation (Al); (iv) the structural units are connected by an *M*4 site occupied by the smallest

88   monovalent B cation (Li). The presence of the smallest possible cations in all the structural sites is

89   likely to determine important crystal-chemical constraints making the incorporation of large cations

90   more difficult than in other amphibole positions. Indeed, ferro-holmquistite (the composition with

91   Fe^{2+} dominant among C cations) occurs rarely (Cámara and Oberti 2005). Because the presence of

92   Fe^{2+} is required to allow the loss of hydrogen (for recent and conclusive work on the mechanism of

93   this process cf. Della Ventura et al. 2018a,b), we have chosen to examine a Fe-rich holmquistite in

94   order to allow quantification of the effects of both thermal expansion and deprotonation upon

95   holmquistite.

96   **EXPERIMENTAL**

97   **Sample: provenance and composition**

98   The crystals used for this study come from the holotype specimen of ferro-holmquistite

99   (Cámara and Oberti 2005) found in the Greenbushes lithian pegmatite, Western Australia, 220 km

100   south of Perth. The sample code 3380B (in the collection of Renato and Adriana Pagano) is used

101   throughout this paper. The Greenbushes zoned pegmatite is one of the world largest producers of

102   tantalum and lithium; the main body has sharply bounded Li-rich, K-rich, and Na-rich zones, the

103   Na-rich zone being in the core. A review of the geology, mineralization, and geochronology of the

104   Greenbushes pegmatite can be found in Partington et al. (1995) and references therein. Associated

105   minerals include albite, quartz, biotite, tourmaline, garnet, tin with tantalite inclusions, zircon, and

106   scapolite (Partington et al. 1995). Holmquistite formed because of lithium migration from the

107   pegmatite into the amphibolite (Frost et al. 1987). It belongs to a late stage and replaces hornblende.

108   Characterization of the sample by Electron MicroProbe (EMP) analyses and single-crystal

109   structure refinement gave a crystal-chemical formula of $^A(K_{0.01}Na_{0.01})$ $^B(Li_{1.88}Mg_{0.08}Na_{0.03}Fe^{2+}_{0.01})$

110   $^C(Al_{1.89}Fe^{2+}_{1.70}Mg_{1.39}Mn^{2+}_{0.02})^TSi_{8.00}O_{22}{}^W[(OH)_{1.97}F_{0.03}]$ for the holotype crystal and is described by

111   Cámara and Oberti (2005). In that work, the Fe^{2+}/Mg ratio was shown to vary in different crystals

112   from the same sample, which coupled with variations in the measured site-scattering values refined

113   at the $M$1-3 sites and in the length of the b edge. Relative to the original ferro-holmquistite crystal

114   studied by Cámara and Oberti (2005), the results of the structure refinement of the crystal used for

115   the present work (3380B n. 7) are displaced by 0.34 *apfu* (atoms per formula unit) $^CFe^{2+}_{-1}$ $^CMg_1$

116   corresponding to a refined site-scattering for the C cations 4.7 electron per formula unit (*epfu*) lower

117   (82.45 *epfu* for crystal n. 7 vs. 87.17 *epfu*. This is the only significant compositional difference

118   observed, and the refined values of site scattering and mean bond-lengths at the individual sites

119   indicate that this exchange occurs mostly at the $M$1 and $M$3 sites ($M$1: 35.44 *epfu and* 2.096 Å, $M$3:

120   18.97 *epfu* and 2.097 Å in crystal n. 7; $M$1: 37.82 *epfu* and 2.100 Å, $M$3: 20.63 *epfu* and 2.102 Å in

121   Cámara and Oberti 2005), whereas those refined for the $M$2 (28.04 *epfu* and 1.931 Å for crystal n.

122   7; 28.72 *epfu* and 1.930 Å in Cámara and Oberti 2005) and the $M$4 (6.70 for crystal n. 7 vs. 7.2

123   e*pfu*) and T sites are more similar. This evidence suggests a composition very close to $^A(K_{0.01}$

5

124   Na$_{0.01}$) ^{B}(Li$_{1.88}$Mg$_{0.10}$Na$_{0.02}$) ^{C}(Mg$_{1.68}$Fe$^{2+}_{1.42}$Mn$^{2+}_{0.02}$Al$_{1.88}$) ^{T}Si$_{8.00}$ O$_{22}$ ^{W}[(OH)$_{1.97}$F$_{0.03}$], and places

125   the crystal studied in this work in the compositional field of holmquistite (because ^{C}Mg > ^{C}Fe^{2+};

126   Hawthorne et al. 2012). A sketch of the holmquistite structure and site nomenclature are given in

127   Figure 1.

Single-crystal XRD analysis (in the T range 298-1023 K)

129   Experimental procedures are the same as those reported in previous studies of orthorhombic

130   amphiboles (Welch et al. 2011a; Zema et al. 2012), and repeated here for the sake of completeness.

131   Before annealing, crystals were mounted on glass fibers, and an ambient data set was collected for

132   structure refinement on a Bruker AXS CCD diffractometer (operating condition in the next

133   paragraph) in order to check for the presence of twins, inclusions or zones with bad crystal quality.

134   Measurements of unit-cell parameters and intensity data collections at HT were done on a Philips

135   PW1100 diffractometer operating with MoKα radiation at 30 mA/55 kV and using a 0.8 mm

136   collimator. For the HT experiment, crystals were loaded into a 0.5 mm diameter quartz capillary and

137   carefully positioned and secured at the sealed tip of the tube by packing with quartz-glass wool. The

138   capillary was then attached to a Huber goniometer head and mounted on the diffractometer. The

139   crystal was aligned optically, and a resistance heater was then placed around it in such a way that

140   the assembly allowed for the incident and diffracted beams to reach and leave the crystal, passing

141   through a kapton window. Geometrical restrictions allowed for the collection of diffracted beam up

142   to ±28° in ω. The furnace was powered by a control unit equipped with a Eurotherm temperature

143   controller, and temperature measured by a K-type thermocouple. Temperature was previously

144   calibrated against the melting points of standard compounds (see, for example, Welch et al. 2011a)

145   and by using the thermal expansion of quartz across the α–β phase transition (a quartz sphere of 0.3

146   mm diameter). Reported temperatures are precise to within ±5 K.

147

148   **Unit-cell parameters**

149   At each working temperature, the orientation matrix was updated by centering 24 reflections

150   selected in the range 8< θ <24°, and then accurate lattice parameters were obtained by a least-

151   squares procedure based on a locally modified version of the Philips LAT routine over 47–55 d^*_{hkl},

152   each measured from the positions of all reflection pairs *h, k, l* and *-h, -k, -l* in the range 3< θ <26°

153   (Cannillo et al. 1983). An explorative experiment was done on a crystal fragment of 0.78 × 0.64 ×

154   0.33 mm^3 (3380B n. 4). Anomalies in thermal expansion, such as non-linear behavior of the *c*

155   parameter, were observed from 623 K, and evidence of the onset of deprotonation was observed at

156   973 K. Isothermal annealing at 1073 K for two days yielded the expected decreases in the unit-cell

157   parameters associated with deprotonation. In order to check whether or not deprotonation was

158   complete, annealing to 1173 K was attempted, but the crystal quality deteriorated quickly. This

159   behavior was different from what observed for other orthorhombic and monoclinic amphiboles with

160   different compositions, which could be annealed up to 1273 K without deterioration. A crystal

161   fragment of 0.20 × 0.35 × 0.55 mm^3 (3380B n. 7) was annealed up to 973 K at steps of 50 K

162   (upward triangles in Figure 2). In order to check whether or not the non-linear behavior of the *c*

163   parameter was reversible, the crystal was first cooled to R*T* in 50 K steps (downward empty

164   triangles in Figure 2) and then heated to 623K, 923K, 948K, 973K, and 1023 K (upward empty

165   triangles in Figure 2) and kept at this temperature for 160 h to allow for deprotonation, which was

166   monitored at intervals of around 24h (empty diamonds in Figure 2). The reversal annealing of the

167   deprotonated crystal was done at steps of 50 K down to R*T* (downward triangles in Figure 2).

168   Measured unit-cell parameters are reported in Table 1 and plotted in Figure 2.

169   **Data collections and structure refinements**

170   Intensity data collections for structure refinements were made on crystal 3380B n. 7 at R*T*,

171   523 and 773 K during the first heating cycle and at R*T* at the end of the whole experiment described

172   above. The R*T* data collection before the heating cycle was done with a Bruker AXS CCD

7

173   diffractometer, ω-rotation frames (scan width 0.2°, scan time 10 s, sample-to detector distance 50

174   mm) were processed with the SAINT software (Bruker, 2003) and intensities were corrected for

175   Lorentz and polarization effects; absorption effects were empirically evaluated by the SADABS

176   software (Krause et al. 2015) and an absorption correction was applied to the data. Accurate unit-

177   cell dimensions were calculated by least-squares refinement of the positions of 8179 independent

178   reflections with $I > 10\ \sigma_I$ in the θ range 2-45°. For the HT data collections and the final RT data

179   collection, all done with a Philips PW1100 diffractometer, a quadrant of intensity data was explored

180   ($\pm h, +k, +l$). Raw intensities were corrected for Lorentz and polarization effects, and a semi-

181   empirical absorption correction based on ψ scans (North et al. 1968) was applied. For all the

182   datasets, unweighted structure refinements based upon F were made in space group $Pnma$ starting

183   from the atom coordinates of Cámara and Oberti (2005). A program written in Pavia was used,

184   which allows the use of neutral versus ionized scattering curves for all the sites where solid solution

185   does not occur, and of combinations of ionized scattering curves for all other sites (Cannillo et al.

186   1983). Scattering factors were taken from the International Tables for X-ray Crystallography (1999)

187   and from Hovestreydt (1983) for O^{2-}. Based on our previous experience of refining amphibole

188   structures, we chose to refine the occupancies of neutral vs. ionized scattering factors for the O and

189   T sites (O vs. O^{2-} and Si vs. Si^{4+}), whereas fully ionized scattering factors for Li^+, Mg^{2+}, Fe^{2+} and

190   Al^{3+} were assigned to the $M$1-4 sites and their relative occupancies were refined. This choice, that

191   does not allow by itself for electroneutrality of the refined model, produces the best estimation of

192   the mean atomic numbers for the $M$1-4 sites. The results of the structure refinements (SREF) are

193   reported in Tables 2-6. The cif files, with F^2_O and $\sigma(F^2_O)$ included, have been deposited as

194   supplementary material.

195   **RESULTS**

196   **Unit-cell parameters and thermoelastic behavior**

197   Figure 2 shows the changes in the unit-cell parameters measured during the annealing cycle.

198   The studied Fe-rich holmquistite has an unusual behavior both before and after deprotonation.

199   During the first heating experiment, a clear non-linear behavior is observed for the *c* parameter.

200   Notably, clear deviations from linear behavior in the thermal expansivity of monoclinic and

201   orthorhombic amphiboles had been so far observed solely (after complete deprotonation) for the *β*

202   angle of the Fe-rich kaersutite DL5 annealed to 1300 K (Oberti et al. 2011; manuscript in

203   preparation) and was ascribed to cation exchange involving the *M*(4) site. A subsequent cooling to

204   R*T* (open symbols in Figure 2) showed that the process causing non linearity is irreversible and is in

205   agreement with the hypothesis of a complex cation exchange process to be discussed in a later

206   section below.

207   Unit-cell dimensions measured during cooling of the partially deprotonated phase show a

208   clear discontinuity at 820-800 K between two linear trends with different slopes for both the *b* and

209   the *c* parameters (Figure 2). This discontinuity has never been noticed in other amphibole

210   compositions. Unfortunately, we do not have structure refinements done before and after the

211   discontinuities. However, because a phase transition with a change of space group can be

212   discounted (we have evidence of the *Pnma* symmetry in all the data collections available), and

213   cation ordering does not occur so rapidly under cooling, these discontinuities are to be related to the

214   unusual crystal-chemistry of holmquistite, and they must reflect the occurrence of topological

215   mismatch/re-arrangement, which will be also investigated in the next section. It is worth noting,

216   however, that without this change in slope (i) the *c* parameter would have converged to the value of

217   the starting composition and (ii) the slope of the *b* parameter observed for the partially deprotonated

218   phase would have been much higher than that of the fully OH phase. Neither of these behaviors has

219   been observed in monoclinic or orthorhombic amphiboles.

220   The evolution with temperature of unit-cell parameters of the studied Fe-rich holmquistite

221   crystal were fitted either with a linear (*a* lattice parameter) or with a *T*-dependent second-order

222   polynomial equation (*b* and *c* lattice parameters) to obtain axial thermal expansion coefficients.

9

223   Both equations were used for unit-cell volume expansion. For the partially deprotonated counterpart

224   of Fe-rich holmquistite, linear fits were carried out in the full T range investigated for the a lattice

225   parameter and limited to 773 K for b, c and V parameters as a discontinuity is observed at that

226   temperature.

227   Least-squares fittings of the experimental data give the following results:

228   Fe-rich holmquistite (RT-923 K): $\alpha_a = 1.36(2)\times10^{-5}$; $\alpha_b = 0.55(1)\times10^{-5}$; $\alpha_c = 1.5(1)\times10^{-5}$ –

229    $6.7(9)\times10^{-9}$; $\alpha_V = 3.5(3)\times10^{-5} – 0.8(3)\times10^{-8}$ (polynomial); $2.58(6)\times10^{-5}$ (linear).

230   Partially deprotonated Fe-rich holmquistite: $\alpha_a = 1.324(9)\times10^{-5}$ (RT-1023 K); $\alpha_b = 0.60(1)\times10^{-5}$

231   (RT-773 K); $\alpha_c = 0.68(2)\times10^{-5}$ (RT-773 K); $\alpha_V = 2.59(2)\times10^{-5}$ (RT-773 K).

232

Unit-cell parameters and deprotonation

234   Similar to the other orthorhombic or monoclinic amphiboles studied so far, a significant

235   shortening in the unit-cell dimensions is observed as a consequence of the deprotonation process,

236   which is locally balanced via oxidation of ^{C}Fe^{2+} (as suggested by the shortening of the $M$1,3-O3 and

237   <$M$1,3-O> bond lengths in Table 4 and 5). However, as shown in the next section, oxidation in this

238   sample occurs solely at the $M$1 site.

239   The amount of the oxo component (^{W}O^{2-}) in the annealed sample can be estimated based on

240   the changes in the $M$1-$M$2 distance measured at RT before and after annealing (Table 5). Although

241   the equations proposed in Figure 29 of Oberti et al. (2007) were calibrated on monoclinic calcium

242   and sodium-calcium amphiboles, their slope is similar (0.054 and 0.051, respectively) in the two

243   subgroups (as well as in sodium-amphiboles; Oberti, unpublished data) and hence can be

244   confidently used also for the orthorhombic amphibole under investigation. The change observed for

245   the two independent $M$1-$M$2 distances at RT before and after the heating cycle is 0.046 Å, which

246   allows for an estimated deprotonation of ~0.85 *apfu* for the Fe-rich holmquistite 3380B n. 7. This

247   value implies that the deprotonation process induced by 160 h at 1023 K does not involve all the

248   available Fe, and that 0.57 residual Fe^{2+} *apfu* are present in the annealed crystal 3380B n. 7 (298R

10

249   in Tables 2-6). This finding is consistent with a smaller shrinking in the unit-cell volume measured

250   at 1023 K for crystal 3380B n. 7 (ΔV = 0.8%) with respect to that measured at 1073 K for the Fe-

251   richer crystal 3380B n. 4 (with total site-scattering of C cations = 85.4) used as a preliminary test at

252   the beginning of this work (ΔV = 1.14%).

253

254   **Cation exchange and Fe oxidation at HT**

255   Pioneering studied done *in situ* by powder neutron diffraction on cummingtonites had

256   showed that temperature induces a significant exchange between B and C cations, and that the

257   entrance of the larger cation in the M(1-3) sites can be detected within two hours. The ^{B}Fe$^{2+}_{-1}$ ^{C}Mg$_{-1}$

258    $_1$^{B}Mg$_1$^{C}Fe$^{2+}_1$ exchange occurs in grunerite at T > 673 K (Reece et al. 2002), and the ^{B}Mn$^{2+}_{-1}$ ^{C}Mg$_{-1}$

259    $_1$^{B}Mg$_1$^{C}Mn$^{2+}_1$ exchange occurs in mangano-cummingtonite at T> 873 K (Reece et al. 2000). This

260   behavior is similar to what observed later in a ^{B}Fe^{2+}-rich pargasite, where Fe^{2+} migration from the

261   M(4) to the M(1-3) sites could be detected at 773 K (in sample Z2124, Oberti et al. 2011). For

262   orthorhombic amphiboles, the HT study of anthophyllite showed a significant Mn^{2+}-Mg exchange,

263   with Mn^{2+} migrating from the $M$4 to the $M$2 site at or beyond 670 K (Welch et al. 2011a). In

264   gedrite, Fe^{2+} was shown to move from the $M$4 site to the $M$1,3 sites beyond 720 K, where it oxidizes

265   to Fe^{3+} during deprotonation at 973 K (Zema et al. 2012). The present experiment was not designed

266   to measure kinetics of cation exchange; we can only state that it can be detected (from the refined

267   site-scattering values; Table 6) already at 523 K.

268   In Table 7, we report our best model of the site populations in crystal 3380B n. 7, which was

269   obtained based on the results of the structure refinement. It is validated by the good agreement

270   observed between the refined and calculated values of the site scattering and of the mean bond-

271   lengths. The crystal-chemical composition of crystal 3380B n. 7 does not allow the ^{B}Fe$^{2+}_{-1}$ ^{C}Mg$_{-1}$

272   ^{B}Mg$_1$^{C}Fe$^{2+}_1$ exchange observed in the other amphibole compositions. Because all Fe is required to

273   be a C cation in order to fit the refined site-scattering values, the only crystal-chemically feasible

11

274   exchange in this sample is the migration of Li$^+$ from the $M$4 to the $M$3 site, which couples with that

275   of the smaller Mg^{2+} ions towards the $M$4 site.

276   During annealing to 773 K, we observe a small but reliable decrease in the site-scattering

277   values refined at the $M$3 site and an increase in those refined at the $M$4 site (Table 6). This

278   observation might in principle be due to a lower quality of the data collected at HT, because the

279   site-scattering values refined at the other sites only show small changes without clear trends, but the

280   refined value of the total number of electrons (Σ(B+C) in Table 6) remains almost constant, thus

281   validating SREF analysis. Also, this trend is confirmed by the RT refinement of the partially

282   deprotonated crystal, where a lower site-scattering value refined at the $M$3 site couples to higher

283   values refined at the other M sites. A tentative pattern of site populations occurring after the

284   annealing cycle is also reported in Table 7, where the oxidation of Fe has been accepted only at the

285    $M$1 site based on the changes in refined site-scattering values and mean bond lengths. These results

286   correspond to a crystal-chemical formula ^{A}(K$_{0.01}$ Na$_{0.01}$) ^{B}(Li$_{1.83}$Mg$_{0.15}$Na$_{0.02}$) ^{C}(Mg$_{1.63}$Fe$^{2+}_{0.57}$

287   Fe$^{3+}_{0.85}$Mn$^{2+}_{0.02}$Al$_{1.88}$ Li$_{0.05}$) ^{T}Si$_{8.00}$ O$_{22}$ ^{W}[O$_{0.85}$(OH$_{1.12}$)F$_{0.03}$]. In conclusion, SREF results are consistent

288   with 0.26 Fe *apfu* migrating from $M$3 to $M$1 (0.08 *apfu*, exchanged with Mg) and especially to $M$2

289   (0.18 *apfu*, exchanged with Al) and of 0.05 Mg *apfu* from $M$3 to $M$4 (exchanged with Li; Table 7).

290   The cation exchange involving the $M$4 site (which is not reversible on cooling, at least under the

291   experimental conditions) is not related to deprotonation and is responsible of the non-linearity

292   observed for the c unit-cell edge in Figure 2. The redistribution of Fe among the $M$1, $M$2 and $M$3

293   sites is most probably related to deprotonation, because its markers, such as the changes in the

294   refined site-scattering values and in the <$M$1-3-O> distances, are evident only in the refinement

295   done at the end of the annealing cycle (298R: Tables 4 and 6, respectively). It is hard to say whether

296   or not the increase of Fe at $M$2 is related to the discontinuities in the B and C trends observed ~820

297   K during reversal, although is difficult to think of a cation exchange occurring quickly and during

298   cooling.

12

299   The contraction of the <$M$1,3-O> distances found in sample 298R are therefore due both to

300   Fe^{2+} oxidation to Fe^{3+} and to this complex cation exchange. The amount of Fe^{3+} required to locally

301   balance deprotonation is ordered at $M$1, as suggested by the refined mean bond-lengths (Table 7),

302   and is coherent with the oxo component formerly evaluated based on the $M$1-$M$2 distance. The

303   mean-square relative deviation from the average (Δ) and quadratic elongation (λ) of the $M$1 and $M$3

304   octahedra also change significantly after deprotonation because of the stronger contraction of the

305   bonds involving the O3 oxygen atoms, especially $M$1-O3A (from 2.094 to 1.986 Å), and the

306   lengthening of the $M$1-O2A,B bonds (from 2.107 to 2.113 Å and from 2.117 to 2.128 Å,

307   respectively). Although the <$M$4-O> distance increases only slightly (2.335 vs. 2.337 Å), the

308   pattern of the individual bond distances changes significantly in the partially deprotonated crystal,

309   where $M$4-O2A, $M$4-O4A,B and $M$4-O5A lengthen whereas $M$4-O2B, and particularly $M$4-O5B

310   and $M$4-O6B shorten. To sum up, thermal annealing does affect significantly both cation

311   distribution and polyhedral geometry.

312

313   **Evolution with T of the coordination polyhedra**

314   Table 4 reports the evolution of the geometrical descriptors of the individual polyhedral in

315   the Fe-rich holmquistite crystal 3380B n. 7, and Table 5 reports the evolution of the individual

316   distances. Note that distances measured at HT have been corrected for riding motion (Busing 1964).

317   As expected, the thermal expansion recorded for the four independent tetrahedra is very low. It is

318   interesting to note, however, that the T1A tetrahedron in the partially deprotonated crystal is

319   significantly smaller (<$T$1-O> from 1.618 to 1.610 Å) although the T1A-O1 distance increases

320   slightly; also, its angular variance at the end of the annealing is less than half that in the crystal

321   before annealing, whereas the quadratic elongation is constant to 1.000. In T1B, the trend is similar

322   but less pronounced in terms of <T1B-O>.

13

323   The mean bond lengths of the $M1$ and $M3$ polyhedra expand almost linearly (Table 5 and

324   Figure 3). The trends are compared in Figure 3 to those available for the other orthorhombic

325   amphiboles.

326   Polyhedral thermal expansivities were calculated for the individual M sites based on the

327   three structure refinement available under the hypothesis of a linear behavior, and are compared to

328   those available for orthorhombic amphiboles in Table 8 and Figure 4. Polyhedra expand less in the

329   studied Fe-rich holmquistite than in anthophyllite (Welch et al. 2011a) and gedrite (Zema et al.

330   2012), confirming that this amphibole composition implies some strong structural constraints.

331   In contrast to gedrite and anthophyllite, the sizes of the $M1$ and $M3$ octahedra in Fe-rich

332   holmquistite are almost identical. Also, their shrinking after the deprotonation process is quite

333   similar. It is important to note, however, that this feature does not depend on the oxidation of

334   similar quantities of Fe in the two sites (actually, almost all Fe oxidation occurs at $M1$) but on the

335   coupling of significant cation exchange (the incorporation of Li$^+$ at the $M3$ site) and of Al disorder

336   between the $M2$ and the $M3$ sites.

337   The $M2$ octahedron has quite an anomalous behavior. In the partially deprotonated crystal,

338   the refined site-scattering increases by ~2 electron per formula unit, and the octahedron becomes

339   larger (<$M2$-O> increases from 1.931 to 1.940 Å), both features being coherent with the increase in

340   Fe^{2+}. However, its shortest bonds, $M2$-O4A and especially $M2$-O4B, shorten (from 1.829 to 1.827 Å

341   and from 1.839 to 1.824 Å, respectively). As a consequence, all the descriptors of the distortions of

342   the octahedron increase significantly after deprotonation. This behavior can be explained by the

343   need for further bond-valence contribution to the O4 oxygen atoms (which coordinate also $M4$ and

344    $T2$A,B, respectively).

345   Focusing on the $M4$ site, Table 5 shows that the $M4$-O6B distance has an unusual behavior,

346   because it shortens during annealing at HT. This behavior can be detected already at 523 K.

347   However, after deprotonation, a further structural rearrangement takes place, and the $M4$ site

348   geometries change accordingly. For instance, the $M4$-O4A and $M4$-O6B in the partly deprotonated

14

349   crystal (2.176 and 2.674 Å, respectively) are longer than in the crystal at 773 K (2.156 and 2.616 Å,

350   respectively).

351

352   **Evolution of the conformation of the double chains of tetrahedra**

353   Figure 4 compares the evolution of the geometry of the double-chains of tetrahedra as a

354   function of *T* and deprotonation in the three orthorhombic compositions of reference. The O5-O6-

355   O5 angle is a measure the kinking along the *c* direction, whereas the *T*1-O7-*T*1-angle is a measure

356   of the bowing along the *a* and *b* directions (red lines and purple arrow, respectively in Figure 1).

357   As a general comment, in the Fe-rich holmquistite of this work, the geometries of the two

358   symmetry-independent double chains of tetrahedra (A: left; B: right) are more similar than in

359   gedrite and anthophyllite. In holmquistite and anthophyllite (Si_8 in the unit formula) all the

360   tetrahedra are occupied by Si, whereas in gedrite (Si_6Al_2 in the unit formula), half of the *T*1

361   tetrahedra are occupied by Al, which has a longer ionic radius than Si. Hence, the two independent

362   Si_8 double-chains in anthophyllite and holmquistite are more stretched than the Si_6Al_2 double-

363   chains in gedrite. Also, they are far less bowed in the studied Fe-rich holmquistite than in

364   anthophyllite and gedrite. Therefore, the kinking and the bowing values measured for Fe-rich

365   holmquistite both indicate a severe strain in the double-chains of tetrahedra.

366   Coherently, H*T* refinements show that the Si_8 double-chains of tetrahedra are far less

367   expansible along *c* in Fe-rich holmquistite than in anthophyllite, which is also in tune with the

368   presence of a much smaller and less expansible *M*2 site occupied by Al (similar to gedrite). It is also

369   interesting to note the very different evolution of the bowing and kinking angles measured after the

370   deprotonation process in Fe-rich holmquistite and in gedrite: the partially deprotonated Fe-rich

371   holmquistite 3380B n. 7 shows almost no change in the kinking of the B double-chain and an

372   increase in that of the A double-chain (whereas gedrite shows a decrease). The increase in the

373   bowing with deprotonation is more significant in Fe-rich holmquistite (Δ bowing = 1.9 and 2,1°,

374   respectively, for the A and B double-chains; H loss = 0.85 apfu) than in gedrite (Δ bowing = 1.9 and

15

375 0.7°, respectively, for the A and B double-chains; H loss = 1.12 apfu), especially for the B double-

376 chain.

377   These observations may spread a new light on the discontinuities observed at 820 K in the b

378 and c parameters during cooling of the partially deprotonated Fe-rich holmquistite of this work,

379 where the double-chains of tetrahedra (especially A) at RT are more stretched and more bowed than

380 in the untreated crystal. The main factor affecting the c edge in amphiboles is the dimension and

381 conformation of the double-chain of tetrahedra, whereas that affecting the b edge is the size of the

382 strip of octahedra (Hawthorne & Oberti 2007). The double-chains of tetrahedra maintain their

383 composition but the strip of octahedra has smaller $M1$ and $M3$ sites but larger $M2$ sites in the

384 partially deprotonated phase. Hence, the different thermal expansivity of the two units may bring to

385 a structural mismatch, which is avoided by a change in conformation of the double-chains of

386 tetrahedra. This in turn implies a change in coordination of the $M4$ site, which indeed is the hinge

387 connecting the two main units of the amphibole structure. This mechanism is perfectly coherent

388 with the available SREF data.

389

390 **The peculiarity of holmquistite among orthorhombic amphiboles**

391   The Fe-rich holmquistite studied in this work has a unique HT behavior, concerning both

392 the non-linear trends observed during annealing at HT for the c edge and the unit-cell volume and,

393 most significantly, the discontinuity in the trends observed for the b and c parameters when cooling

394 the partially deprotonated phase. The non-linearity of the c parameters in Fe-rich holmquistite

395 disappears in the reversal experiment, and is related to the (irreversible) $^{M4}Li_{-1}{}^{M3}Mg_{-1}{}^{M4}Mg_1{}^{M3}Li_1$

396 exchange. The discontinuity in the α_b and α_c trends in the partially deprotonated phase derives both

397 from the cation exchanges involving the nature and distribution of ^CFe (enrichment and oxidation of

398 Fe^{2+} at the $M1$ site and disorder of Al between the $M2$ and $M3$ sites) and some geometrical

399 constraint related to the matching of the double-chains of tetrahedra with the strip of octahedra. In

400 particular, a comparison between the structures of the untreated and of the partially deprotonated

401 crystal suggests changes in the conformation of the double-chains of tetrahedra.

402   In order to confirm this conclusion, further H*T* structure refinements are required on the

403 partially deprotonated phase, but they should be done on a Fe-poor compositions which are

404 expected to be more stable.

405

406 **Constraints for the H*T* behavior of orthorhombic amphiboles**

407   The work done so far on the H*T* behavior of orthorhombic amphiboles allows fixing some

408 general rules:

409   1. The presence of two symmetry-independent double-chains of tetrahedra in space group

410   *Pnma* allows different conformations of the chains around the A and B cations and different

411   responses to thermal expansion and deprotonation. A cooperative effect of the A cations on

412   the deprotonation process was indeed observed in gedrite, which has preferential H loss at

413   O3A (Zema et al. 2012).

414   2. The loss of the protons implies significant changes (contraction) in unit-cell parameters

415   (hence in molar volume) as well as in site populations and polyhedral geometry. The

416   contraction in molar volume, however, is always smaller than thermal expansion.

417   3. The major factors affecting thermal behavior in orthorhombic amphiboles are the nature of

418   the B cations, the Fe^{2+} content and the balance of the effects of Al occurring as a C or T

419   cation. The greater stiffness of the holmquistite structure is determined by the dominance of

420   Li at the *M*4 site. Whereas ^{C}Al limits the expansion of the strip of octahedra, ^{T}Al provides

421   more flexibility to the double-chains of tetrahedra.

422   4. The critical factor allowing deprotonation is the availability of Fe^{2+}, both as a C or as a B

423   cation. $^{B}Fe^{2+}$ is involved in the process *via* a $Fe^{2+} \leftrightarrow Mg$ exchange between the *M*4 and the

424   *M*1,3 sites, which is particularly important in gedrite, where migration of $^{B}Fe^{2+}$ starts around

17

425   700 K. In the studied Fe-rich holmquistite, only a redistribution of Fe^{2+} among the $M$1-3

426   sites could be observed, while Fe oxidation occurs only at the $M$1 site. Also, in this case

427   deprotonation does not proceed until consumption of Fe^{2+}. Actually, some Fe^{2+} migrates to

428   the $M$2 site, where it is no longer available to maintain local electroneutrality at the O(3)

429   oxygen atom.

430

IMPLICATIONS

432   Amphiboles are a widespread mineral phase in rocks of very different origin and

433   composition. They are considered one of the most useful markers of rock evolution, because they

434   are sensitive to changes in both composition and T and P condition of the system, and also because

435   their cation ordering strongly depends on the T and P conditions of closure (reviewed by Oberti et

436   al. 2007). Also, at high T amphibole may release significant amounts of H^+, which combines with

437   O_2 at the crystal surface to produce H_2O. The first attempts to understand the mechanism and the

438   dynamics of H^+ release and migration are reported in Della Ventura et al. (2018a,b). Also, the work

439   done in Pavia on orthorhombic and monoclinic amphiboles (the published parts are cited in the

440   introduction) shows that the onset T for deprotonation strongly depends on composition.

441   How, when and how much H_2O is released during geological processes is certainly an

442   important issue for petrological studies and their related thermodynamic models, especially in

443   subduction-related processes, where deprotonation and dehydration reactions are relevant because

444   they affect rheological properties. Hence, developing a comprehensive crystal-chemical model of

445   the HT behavior and of the deprotonation process in amphiboles based upon quantitative crystal-

446   chemical knowledge is an important goal. However, this model must take into account all the

447   relevant variables (composition, cation ordering, and perhaps also symmetry) and, thus, requires a

448   large amount of experimental work on different compositions. This work provides the required data

449   for compositions of pertinence to one of the fourth rootname of orthorhombic amphiboles,

18

450 holmquistite, but also allows prediction of the behavior of the other Li rich compositions of

451 monoclinic amphiboles.

FIGURE 1. The crystal structure of Fe-rich holmquistite 3380B n.7 at RT projected onto (100). The relevant site nomenclature is shown according to Hawthorne and Oberti (2007). The red line indicates the kinking angle (O5-O6-O5), and the purple arrow the bowing angle ($T$1-O7-$T$1) for the B double-chain of tetrahedra.

FIGURE 2. Changes in unit-cell parameters measured for Fe-rich holmquistite 3380B n. 7 during thermal annealing. All events recorded are reported in the graph: first heating to 923K (upward solid triangles); cooling to RT (downward empty triangles); re-heating up to 1023K (empty upward triangles); isothermal annealing at 1023K for 160 h (empty diamonds) showing contraction of all parameters due to the occurring of the deprotonation process; final cooling to RT of the deprotonated crystal (downward solid triangles).

FIGURE 3. Changes in mean bond-lengths (corrected by riding motion) at the $M$1-3 octahedra and at the $M$4 [6+2] coordinated site observed during annealing in anthophyllite (left), gedrite (middle) and Fe-rich holmquistite 3380 n. 7 (right). Solid symbols: the original crystal; empty symbols: the deprotonated crystal.

FIGURE 4. The evolution of the volumes of the individual polyhedra in holmquistite and in the other orthorhombic amphiboles studied so far. The calculated thermal expansivities are reported and compared in Table 8.

FIGURE 5. Changes in the kinking (O5-O6-O5) and bowing ($T$1-O7-$T$1) angles in the two independent double chains of tetrahedra (A and B) measured in orthorhombic amphiboles during thermal annealing. Solid symbols: the original crystal; empty symbols: the deprotonated crystal.

* Calculated based on the <cation-O> distances modelled for monoclinic amphiboles

** The oxo component has been calculated based on the difference between the refined $M1$-$M2$ distances (cf. text for more detail)

9

Table 8. Comparison of the thermal volume expansivities of individual polyhedra ($\times\ 10^{-5}$ K^{-1}) measured for the three orthorhombic amphiboles of petrological relevance. Fe-rich Hol (this work); Ath = anthophyllite (Welch et al. 2011); Ged = gedrite (Zema et al. 2012). R = reversal experiments on the partially deprotonated phase. Site nomenclature after Hawthorne et al. (2012), mineral abbreviations according to Whitney and Evans (2010).

Sample	*M*1	*M*2	*M*3	*M*4
Fe-rich Hol	2.65(2)	1.8(16)	2.0(5)	5.7(3)
Ath	4.4(1)	4.6(3)	4.09(3)	7.0(2)
Ged	4.6(3)	4.4(4)	4.94(7)	5.8(3)
Ged R	5.4(5)	2.3(5)	5.3(9)	7.1(3)

10

FIGURE 1. The crystal structure of Fe-rich holmquistite 3380B n.7 at R*T* projected onto (100). The relevant site nomenclature is shown according to Hawthorne and Oberti (2007). The red line indicates the kinking angle (O5-O6-O5), and the purple arrow the bowing angle (*T*1-O7-*T*1) for the B double-chain of tetrahedra.
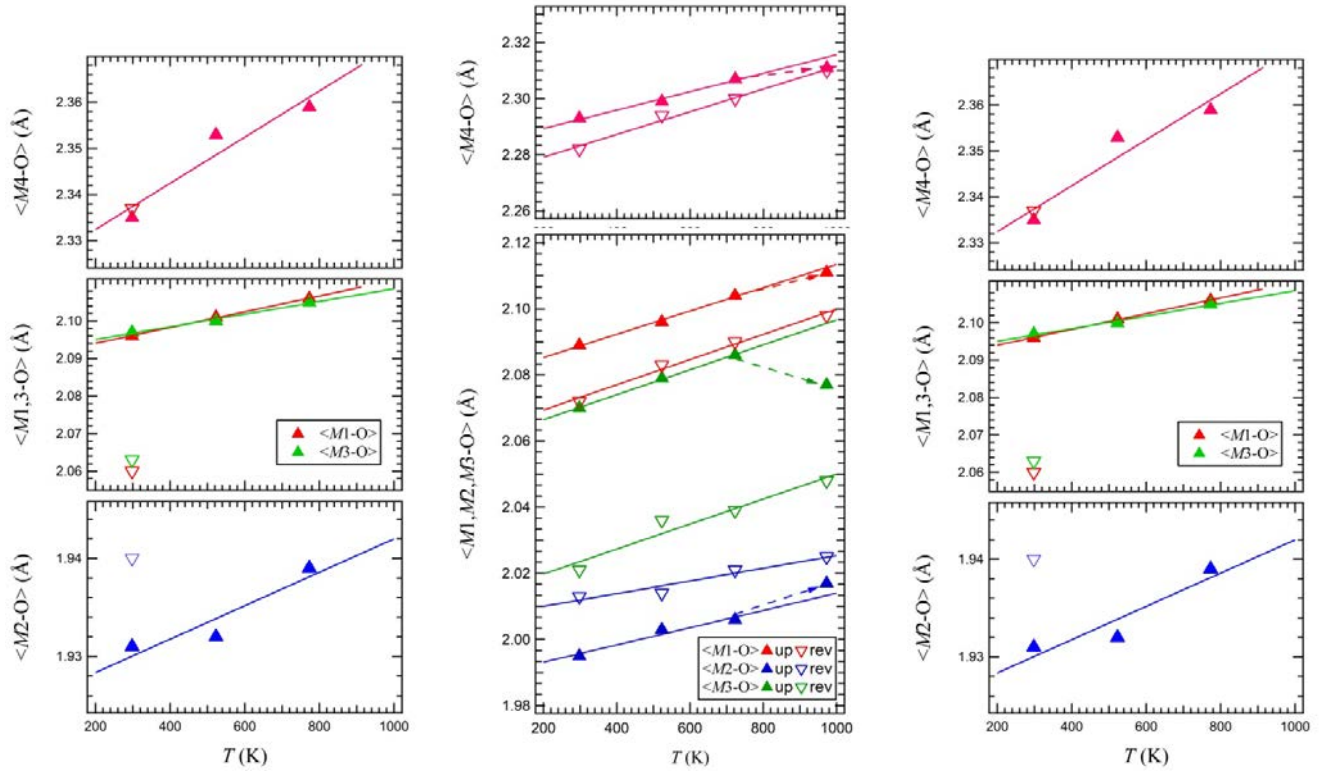

FIGURE 2. Changes in unit-cell parameters measured for Fe-rich holmquistite 3380B n. 7 during thermal annealing. All events recorded are reported in the graph: first heating to 923K (upward solid triangles); cooling to R*T* (downward empty triangles); re-heating up to 1023K (empty upward triangles); isothermal annealing at 1023K for 160 h (empty diamonds) showing contraction of all parameters due to the occurring of the deprotonation process; final cooling to R*T* of the deprotonated crystal (downward solid triangles).
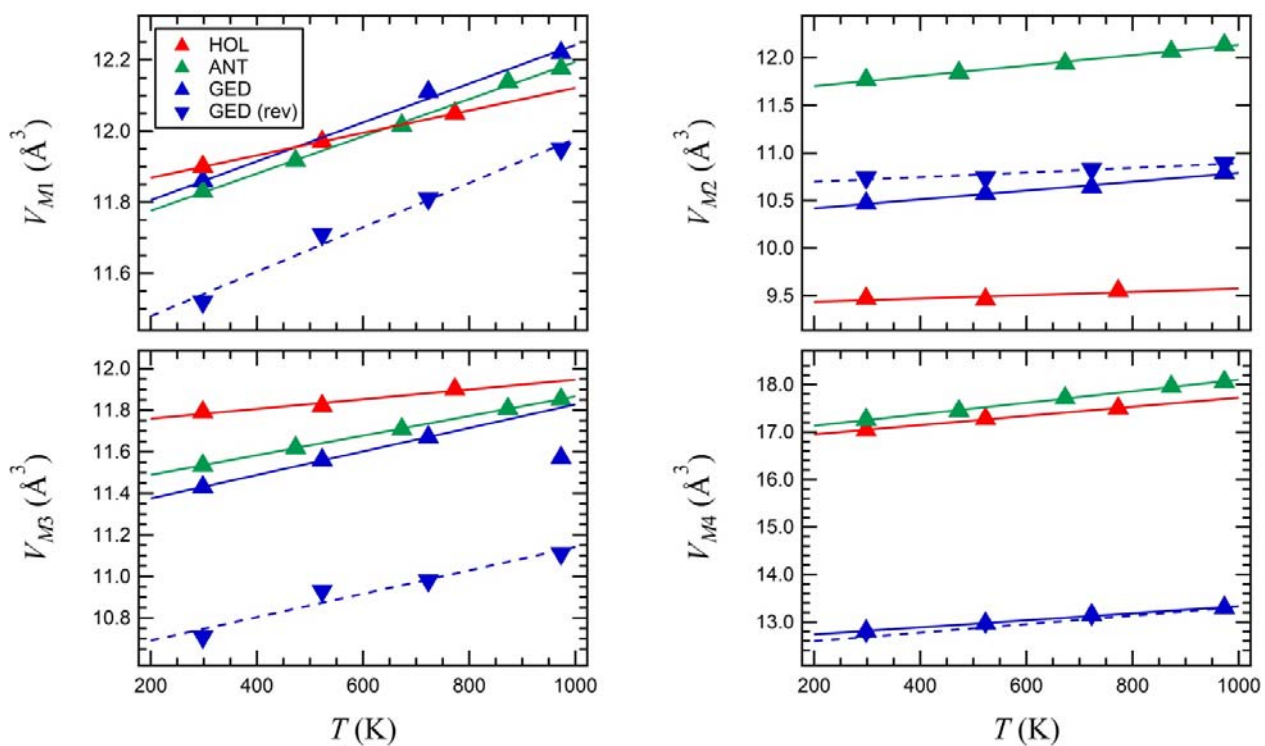

FIGURE 3. Changes in mean bond-lengths (corrected by riding motion) at the $M$1-3 octahedra and at the $M$4 [6+2] coordinated site observed during annealing in anthophyllite (left), gedrite (middle) and Fe-rich holmquistite 3380 n. 7 (right). Solid symbols: the original crystal; empty symbols: the deprotonated crystal.
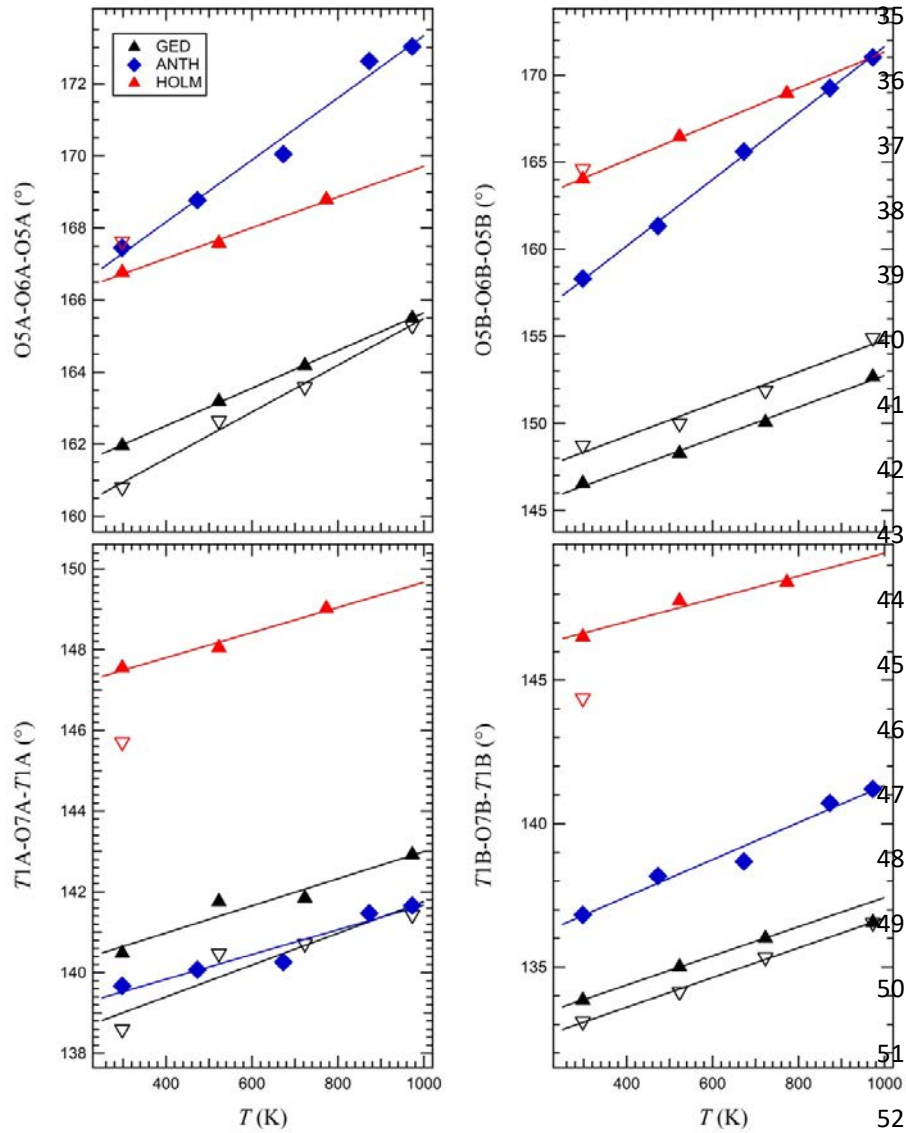

FIGURE 4. The evolution of the volumes of the individual polyhedra in holmquistite and in the other orthorhombic amphiboles studied so far. The calculated thermal expansivities are reported and compared in Table 8.

FIGURE 5. Changes in the kinking (O5-O6-O5) and bowing ($T1$-O7-$T$1) angles in the two independent double chains of tetrahedra (A and B) measured in orthorhombic amphiboles during thermal annealing. Solid symbols: the original crystal; empty symbols: the deprotonated crystal.
