26   **ABSTRACT**

27

28   X-ray diffraction analysis and ultrasonic measurements of glass with a pyrope

29   composition were conducted to determine its structural and elastic properties at pressures ranging

30   from 1 atm to 12.9 GPa. Our results indicated that the structural evolution in the glass was

31   closely related to changes in the compression wave velocity (V_P), the shear wave velocity (V_S),

32   and the Poisson ratio. We observed three modes of pyrope glass compression. Moderate

33   shrinkage in the intermediate-range ordered structure occurred at pressures below 6 GPa.

34   Significant shrinkage in the intermediate-range ordering was observed at pressures between 6

35   GPa and 9 GPa. We observed changes in the short-range ordered structure at pressures above 9

36   GPa, which were associated with an increase in the coordination number of tetrahedral cations.

37   The absolute values of V_P and V_S in pyrope glass were similar to those in magnesium-bearing

38   silicate glasses with enstatite and diopside compositions. However, the velocities were higher

39   than those observed in sodium aluminum silicate glasses with jadeite and albite compositions.

40   This indicated that the absolute values were governed by the initial density of the glass, which

41   was determined by its chemical composition. In terms of pressure, the velocity minimum in

42   pyrope glass was observed at ~5 GPa, which was similar to the velocity minima in fully

43   polymerized glasses, such as jadeite and albite. The degree of polymerization in the pyrope glass

44   was intermediate, and it had a relatively polymerized network. A drastic increase in velocity was

45   observed when the pyrope glass was subjected to pressures above 7–8 GPa, and the velocity

46   exceeded that observed in silicate glasses. Densification phenomenon, such as an increase in the

Revision 2

47   Al coordination number, was efficiently promoted. This was because the cationic field strength

48   of Mg^{2+} exceeded that of typical non-network forming cations. Magnesium cations may have an

49   important role in controlling the behavior of silicate glass, and partially melted mantle becomes

50   enriched with Mg under pressure. Studying Mg-bearing aluminosilicate glasses can thus help us

51   to better understand the behavior of magma deep in the interior of the Earth.

52

54

55   **Introduction**

56

57   The atomic structures of magmas are closely related to their physical, chemical, and

58   thermal properties (Mysen et al. 1982; 1985; Kushiro and Mysen 2002). Examining silicate

59   glasses can provide insight into magma structure. Many analytical methods have been used to

60   investigate pressure-induced structural and physical changes in silicate (SiO_2) glasses. These

61   include Raman spectroscopy (McMillan et al. 1984; Devine and Arndt 1987), X-ray diffraction

62   analysis (Meade et al. 1992; Inamura et al. 2004; Sato and Funamori 2010), neutron diffraction

63   analysis (Inamura et al. 2001), molecular dynamics simulation (Jin et al. 1994; Trachenko and

64   Dove 2002, 2003), Brillouin scattering analysis (Zha et al. 1994; Murakami and Bass 2010), and

65   ultrasonic techniques (Yokoyama et al. 2010; Kono et al. 2012). A large increase in density of

66   glasses is attributed to a significant shrinkage of the intermediate-range order (IRO) network,

67   which is indicated by a drastic change in the first sharp diffraction peak (FSDP) in the structure

68   factor, $S(Q)$ (Susman et al. 1991; Inamura et al. 2001; Trachenko and Dove 2002).

69   Aluminum is one of the most abundant elements on Earth, and it significantly influences

Revision 2

70　the properties of silicate networks in melts and glasses. Al^{3+} is an intermediate species in silicate

71　melts, meaning that it can be incorporated into a network modified depending on the

72　composition (Riebling 1966; Mysen et al. 1981). In fully polymerized melts, such as jadeite and

73　albite, all of the TO_4 tetrahedra (T = Si^{4+}, Al^{3+}) are linked by shared oxygen anions and form a

74　three-dimensional network structure. Alkali metal ions, such as Na^+ and K^+, and alkali earth

75　metal ions, including Mg^{2+} and Ca^{2+}, can also affect the behavior of melts. These cations are

76　known as network modifiers, and they can break the Si–O–Si bonds that join adjacent SiO_4

77　tetrahedra (Mysen et al. 1982).

78　　　　An increase in the coordination number (CN), or the number of coordinated oxygen

79　atoms around a network-forming metal, leads to densification during pressure-induced structural

80　evolution. Nuclear magnetic resonance (NMR) spectroscopy studies of aluminosilicate glasses

81　have shown that the Al–O CN increases at lower pressures than the Si–O CN (Stebbins and

82　Sykes 1990; Yarger et al. 1995; Lee et al. 2004; Allwardt et al. 2007). Based on the results of

83　these NMR studies, an increase in the Al–O CN is affected by the field strengths of cationic

84　modifiers. The cationic field strength is equal to the charge of the cation divided by the square of

85　the distance between the cation and an oxygen atom (Allwardt et al. 2005, 2007; Kelsey et al.

86　2009). In other words, modifiers with high cationic field strengths promote increases in the Al–O

87　CN. The cationic field strengths of alkali and alkali earth metal cations follow the order K < Na

88　< Ca < Mg, which means that Mg-aluminosilicate glasses can undergo structural changes at

89　relatively low pressures (McMillan and Kirkpatrick 1992; Toplis et al. 2000; Neuville et al.

90　2008).

91　　　　Pyrope ($Mg_3Al_2Si_3O_{12}$) is a Mg-aluminosilicate mineral that is abundant in the Earth's

92　upper mantle. A change in the slope of the pyrope melting curve from approximately 7 GPa to 10

Revision 2

93   GPa suggests that pressure induces a change in aluminum coordination (Irifune and Ohtani 1986;

94   Zhang and Herzberg 1994). The structures and elasticity of Mg-aluminosilicate glasses have

95   been investigated extensively via neutron and X-ray diffraction analysis (Guignard and Cormier,

96   2008) and NMR spectroscopy (McMillan and Kirkpatrick, 1992; Toplis et al. 2000; Neuville et

97   al. 2008). Those of pyrope glasses have been studied at ambient pressure via XRD analysis

98   (Okuno and Marumo 1997) and NMR spectroscopy (Lee et al. 2016). However, the properties of

99   pyrope at high pressures are poorly understood.

100   In this study, we investigated the elastic wave velocities in pyrope glass at pressures

101   ranging up to 12.9 GPa using a pulse-echo overlap ultrasonic technique to better understand the

102   dependence of its elastic properties on pressure. Information about the structure of the glass at

103   pressures up to 12.9 GPa was obtained by performing multi-angle energy-dispersive X-ray

104   diffraction analysis. Herein we describe pressure-induced changes in the wave velocity in pyrope

105   glass and its structure, and we discuss the relationship between its elastic properties and

106   structural evolution.

107

108   **Experimental Methods**

109   Reagent grade SiO_2, MgO, and Al_2O_3 were mixed to obtain a pyrope composition

110   ($Mg_3Al_2Si_3O_{12}$) in an agate mortar with acetone for 1 h. The mixed powder was melted at 1,873

111   K and quenched to ambient temperature to form the glass. In glass with a pyrope composition,

112   the ratio of non-bridging oxygen (NBO) anions to tetrahedrally coordinated cations (T), or

113   NBO/T, is 0.8 (Mysen et al. 1982). The NBO/T ratio in a silicate network is a fundamental

114   indicator of its degree of polymerization. A fully polymerized network has an NBO/T ratio of 0,

115   while a TO_4 monomer assembly has an NBO/T ratio of 4. Based on the NBO/T ratio of pyrope

Revision 2

116   glass (0.8), it has a relatively polymerized structure.

117   For our structural investigations, we performed energy-dispersive X-ray diffraction

118   analysis at pressures ranging from 1 atm to 12.9 GPa using the PF-AR NE5C beamline at the

119   High Energy Accelerator Research Organization (KEK) Facility in Tsukuba, Japan. We used a

120   MAX80 cubic multi-anvil apparatus (Shimomura et al. 1984) in combination with MA6-6

121   assembly (Nishiyama et al. 2008) to generate high pressures. The incident X-ray beam was

122   collimated by directing it through two sets of 0.1 mm vertical slits and 0.2 mm horizontal slits.

123   The diffracted beam was collimated by placing a 0.1 mm gap collimator 43 mm downstream

124   from the sample and two receiving slits 40 mm downstream from the scattering slits. A 0.2 mm

125   vertical receiving slit and either a 0.3 mm ($2\theta \leq 8°$) or 1.0 mm ($2\theta \geq 11°$) horizontal receiving

126   slit were used. A Ge solid-state detector (Ge-SSD) with a 2048 multichannel analyzer was

127   mounted on a two theta arm, which enabled us to accurately control the diffraction angle.

128   Diffraction patterns were collected at fixed diffraction angles (2θ) of 3°, 4°, 5°, 6°, 8°, 11°, 14°,

129   17°, 21°, 25°, and 30°. Collection times varied and depended on the diffraction angle, since the

130   intensity decreased as 2θ increased. Pattern collection continued until the maximum intensity

131   reached at least 7,000 counts. An example of diffraction patterns of pyrope glass is shown in

132   Figure 1. The connection of multiple data sets collected at various 2θ angles was conducted to

133   minimize the differences between intensity patterns in each overlap region. This procedure has

134   been performed based on the Monte Carlo simulation method (MCEDX) developed by

135   Funakoshi (1997). This method enables us to obtain the reliable intensity profile without using

136   any theoretical functions. The structure factor, $S(Q)$, was obtained from the X-ray diffraction data

137   using the MCEDX analytical program. $S(Q)$ is given by Equation (1).

Revision 2

$$S(Q) = \left\{ I^{\mathrm{coh}}(Q)/N - \sum_i c_i [f_i(Q)]^2 \right\} \Big/ \left[\sum_i c_i f_i(Q) \right]^2 + 1, \tag{1}$$

138   where N is the number of atoms and $I^{\mathrm{coh}}(Q)$ is the coherent intensity due to atomic correlation. c_i

139   and $f_i(Q)$ are the concentration and the atomic scattering factor of the ith atom, respectively. The

140   summation is taken over the atomic species. Q is the magnitude of the scattering vector given by

141   Equation (2).

$$Q = \frac{4\pi E \sin\theta}{hc} = \frac{4\pi \sin\theta}{\lambda}, \tag{2}$$

142   where λ is the X-ray wavelength, E is the X-ray energy, θ is half of the diffraction angle, h is

143   Planck's constant, and c is the speed of light in a vacuum. The local structure in real space is

144   given by the pair distribution function, $g(r)$ (Kaplow et al. 1965), which is the Fourier transform

145   of $S(Q)$ according to Equation (3).

$$g(r) = 1 + \frac{1}{2\pi^2 nr} \int_{Q_{\mathrm{min}}}^{Q_{\mathrm{max}}} Q[S(Q) - 1]\sin(Qr)\mathrm{d}r, \tag{3}$$

146   where n is the number density, and r is the radial distance.

147   Ultrasonic experiments to measure elastic wave velocities were conducted at pressures of

148   up to 12.9 GPa using a SPEED-1500 Kawai multi-anvil apparatus installed on the BL04B1

149   beamline at SPring-8 (Utsumi et al. 1998). Cobalt-doped magnesia was used as the pressure

150   medium. The sample was sandwiched between fully densified alumina cylinders, which served

151   as a buffer rod and back-reflector. The top and bottom surfaces of the glass sample, the alumina

152   buffer rod, and the back-reflector were polished with diamond paste (1 μm) to ensure good

153   mechanical contact. Two pieces of gold foil were placed on the top and bottom of the sample as

154   markers for length measurements. Radiographs were collected using a CCD camera to determine

155   the length of the sample under high pressures. The pressures were determined using the NaCl

Revision 2

156   equation of state (Decker 1971). The scattered X-rays were detected using a Ge SSD paired with

157   a 4096 multichannel analyzer. High-pressure elastic wave velocity measurements were

158   performed using the ultrasonic pulse-echo overlap method. A 10° rotated Y-cut LiNbO$_3$

159   transducer was used as the ultrasonic signal generator and receiver. The signals were recorded at

160   a sampling rate of 1×10^{10} points per second. Detailed descriptions of the ultrasonic

161   measurements can be found in Higo et al. (2008, 2009, 2018). An example of X-ray radiography

162   image and ultrasonic signal is shown in Figure 2. At an ultrasonic wave frequency of 42 MHz,

163   the accuracy of the travel time is not less than one tenth of the period, ~2.4 ns (Higo et al. 2009).

164   An uncertainty of ±2.4 ns in the travel time generated uncertainties of no more than ±0.95% and

165   ±0.68% in the compression and shear wave velocities, respectively. An uncertainty of <1 pixel in

166   the sample length was a conservative estimate, because the positions of the sample interfaces

167   with the buffer rod and back-reflector were determined with a standard deviation of <1.8 pixel.

168   An uncertainty of ±1.8 pixel in the sample length corresponded to an error of ±0.31% in

169   measurements of both compression and shear wave velocity. We concluded that the overall

170   uncertainties in the compression and shear wave velocity measurements were less than 1.00%

171   and ±0.74%, respectively.

172   **Results and Discussion**

173   **Structure of pyrope glass under pressure**

174

175   The structure of pyrope glass was analyzed at pressures ranging from 1 atm to 12.9 GPa.

176   The structure factor obtained at each pressure is shown in Fig. 3. For silicates, the FSDP is

177   typically centered at 2–3 Å^{-1} in the $S(Q)$. This is indicated by the solid arrow in Fig. 3. The

178   FSDP is generally a signature of the …–T–O–T–… IRO structure in a silicate network (Elliott

Revision 2

179   1991). The FSDP positions of various silicate glasses under pressure are shown in Fig. 4. The

180   FSDP position under ambient conditions is associated with the void volume in the network

181   structure (e.g., Onodera et al. 2019) of the glass, which is mainly governed by its chemical

182   composition. Pure silica glass has the spongiest network, while sodium aluminosilicates (albite,

183   jadeite) have smaller void volumes. The void volume in magnesium aluminosilicate (pyrope)

184   glass is smaller still, and calcium magnesium silicate (diopside) glasses have the lowest void

185   volumes. In other words, the relationship between pressure and the FSDP position is governed by

186   the combination of metal cations in the silicate glass. The FSDP position of pyrope glass at

187   ambient pressure is between those of albite/jadeite glass and diopside glass. In terms of the

188   dependence of the FSDP position on pressure, a shift in the peak to a higher Q indicates

189   pressure-induced shrinkage of the IRO structure in real space. This corresponds to a change in

190   the network TO_4 configuration, such as a decrease in the tetrahedral T–O–T bond angle and a

191   reduction in the void volume in the network. The FSDP positions of pyrope and depolymerized

192   glasses are less sensitive to pressure than those of fully depolymerized glass. Wang et al. (2014)

193   investigated the dichotomy between pressure and the FSDP position using structural data from

194   both X-ray diffraction and molecular dynamics analyses of the jadeite-diopside join. They

195   observed an interesting phenomenon in a fully polymerized jadeite melt. The number of bridging

196   oxygen (BO) atoms monotonically decreased with increasing pressure. This indicated that the

197   fully polymerized melt had a spongy structure. Since every oxygen anion was a BO, the initial

198   response to pressure was a decrease in the T–O–T bond angle, which resulted in bond breakage

199   in the continuous network. The first stage of compression thus involved a pressure-induced

200   decrease in the BO population, i.e. depolymerization. In contrast, an increase in the BO

201   population and a monotonic decrease in the NBO population were observed in the

202   depolymerized diopside melt. Due to the reduced connectivity of its TO_4 network, the

203   depolymerized diopside melt had a much weaker structure that could rearrange without breaking

204   many BO bonds. A rapid decrease in the NBO population with pressure caused the structure to

205   polymerize. Similar behavior has been observed in depolymerized MgO-SiO_2 glasses under

206   pressure (Wilding et al. 2012).

207   Since the network in pyrope glass is moderately polymerized (NBO/T = 0.8), the FSDP

208   position of pyrope glass is affected less by pressure than those of fully polymerized glasses. A

209   monotonic shift in the FSDP toward higher Q values was observed as the pressure increased up

210   to 7.1 GPa (Fig. 4), which suggested continuous shrinkage of the IRO network structure. The

211   FSDP position underwent a relatively large shift to higher Q values at pressures between 7.1 GPa

212   and 8.8 GPa, and the shift continued monotonically up to 12.9 GPa.

213   The local structure in the glass was determined from the pair distribution function, $g(r)$,

214   which was obtained by performing a Fourier transformation of $S(Q)$ (Eq. 3). Variations in the

215   $g(r)$ of the pyrope glass with pressure are shown in Fig. 5. The peak near 1.6–1.7 Å corresponded

216   to T–O, or the length of the bonds between tetrahedrally coordinated cations and oxygen anions

217   in the pyrope glass. The Mg^{2+}/Al^{3+} molar ratio in pyrope glass is 1.5. All of the Al cations in the

218   glass are incorporated into the network, while interstitial Mg cations balance the charge. The

219   shoulder peaks in the ranges of 2.0–2.2 Å and 2.6–2.8 Å represented the Mg–O and O–O bond

220   distances, respectively. The positions of these peaks were consistent with those reported by

221   Okuno and Marumo (1993) at ambient pressure. The peak observed near 1.6–1.7 Å did not have

222   any distinctive features that would enable us to distinguish between Si–O and Al–O bonds, so it

223   was taken as the average of the Si–O and Al–O bond distances. It is important to determine the

224   T–O bond length to understand the properties of the TO_4 tetrahedra, which are the basic units of

Revision 2

225   silicate glass. The T–O bond length in pyrope glass is shown as a function of pressure in Fig. 6.

226   The Si–O and Al–O bond lengths in crystalline pyrope (Zhang et al. 1998) are plotted for

227   comparison. The length of T–O bonds in pyrope glass remained stable up to 11.6 GPa, then

228   increased. The T–O peak broadened near 12.9 GPa. This implied that the average CN of

229   tetrahedrally coordinated cations increased near 13 GPa. In contrast, the Si–O and Al–O bond

230   lengths in crystalline pyrope slightly decreased with pressure.

231   Al is much more susceptible to changes in coordination than Si (Waff 1975; Yarger et al.

232   1995; Lee et al. 2004). The fraction of highly coordinated Al (i.e. [5,6]Al) in ternary

233   aluminosilicate glasses also increases as the cationic field strengths of network-modifying

234   cations increase (Neuville et al. 2008; Kelsey et al. 2008; Ifterkhar et al. 2012; Jaworski et al.

235   2012), and the cationic field strength of Mg^{2+} is higher than that of Na^+, K^+, and Ca^{2+} (McMillan

236   and Kirkpatrick 1992; Toplis et al. 2000; Neuville et al. 2008).

237   The T–T bond length near 3.1 Å provided information about the relationship between

238   adjacent TO_4 tetrahedra, which was important for understanding the three-dimensional (3D)

239   nature of the glass structure. The calculated average T–O–T bond angles were based on the

240   relationship between the T–O and T–T bond lengths. The T–O–T angle was set equal to

241   2arcsin{[T–T]/2[T–O]} assuming that corner-sharing TO_4 tetrahedra formed a 3D framework

242   structure. The dependence of the T–O bond length, the T–T bond length, and the T–O–T angle in

243   pyrope glass on pressure is illustrated in Fig. 7. The T–T bond length was more sensitive to

244   pressure than that of T–O. Broadening of the T–T peaks above 7.1 GPa could have been due to

245   topological disordering. The dependence of the T–O–T angle on pressure followed a similar

246   trend to that observed in the T–T bond length. The T–O–T angle decreased by 6.9% from 141.4°

247   at 1 atm to 131.7° at 12.9 GPa. The T–O–T angle was closely related to the IRO network

248   structure, and a decrease in the T–O–T angle indicated a transition to a more compact structure.

249   This compression may have been related to an increase in the proportion of edge-sharing TO_4

250   tetrahedra relative to corner-sharing TO_4 tetrahedra.

251   Crystalline pyrope has a cubic structure with Si and Al CNs of 4 and 6, respectively

252   (Novak and Gibbs 1971). SiO_4 tetrahedra and AlO_6 octahedra share corners to form the 3D

253   network. Cavities within the network structure can be viewed as distorted cubes comprised of

254   eight oxygen atoms surrounding a Mg cation. Therefore, oxygen is bonded to one Si, one Al, and

255   two Mg. The Si–O–Al angle in crystalline pyrope decreases from 131.0° at ambient pressure to

256   128.8° at 11.53 GPa (Zhang et al. 1998). This decrease was far less pronounced than the changes

257   in the T–O–T angle in pyrope glass observed in this pressure range. The structure of pyrope glass

258   differs significantly from that of crystalline pyrope in terms of Al coordination. Lee et al. (2016)

259   investigated the environment around Al in pyrope glass at ambient pressure via NMR

260   spectroscopy. Most of the Al in pyrope glass has a CN of 4, and the amount of [5,6]Al ranges from

261   ~7% to 10%. In other words, the CN of Al in pyrope glass differs from the CN of Al in

262   crystalline pyrope.

263

264   **Elastic wave velocities in pyrope glass under pressure**

265

266   The experimental elastic wave velocity measurements are summarized in Table 1. The

267   dependencies of the compression wave velocity (V_P) and shear wave velocity (V_S) on pressure

268   are illustrated in Figs. 8 and 9, respectively. The velocities in silica (Zha et al. 1994), jadeite,

269   albite, diopside (Sakamaki et al. 2014), and enstatite glasses (Sanchez-Valle and Bass 2010) are

270   plotted for comparison. The velocities at ambient pressure were governed by the chemical

Revision 2

271   composition, particularly the Mg content. According to Birch's law, there is a linear relationship

272   between density and velocity at a constant mean atomic weight (Birch 1961). This means that the

273   velocities in magnesium-bearing silicate glasses are much higher than those in less dense,

274   magnesium-free glasses.

275   Marked changes in the elastic wave velocities in pyrope glass were observed in three

276   pressure regions. At pressures below 6 GPa, the slopes of the elastic wave velocities were

277   negative. At pressures between 6 GPa and 9 GPa, the velocities increased sharply with pressure.

278   At pressures above 9 GPa, increases in the velocities were moderate. In terms of composition,

279   the impact of pressure on velocity was either the appearance of a velocity minimum or the

280   absence of a minimum. These results indicated that the degree of polymerization fundamentally

281   affected the behavior of compressed silicate glass. In polymerized glasses, both the V_P and V_S

282   initially decreased with pressure, then increased above a threshold pressure. Softening was much

283   more pronounced in the V_S than the V_P. This can be seen in Figs. 8 and 9. In contrast, the V_P and

284   V_S in depolymerized glasses, such as diopside and enstatite glasses, changed only slightly as the

285   pressure increased. This behavior differed from that observed in the polymerized glasses. The

286   marked differences between the impacts of pressure on the elastic wave velocities suggested that

287   the dominant structural changes in the glasses in each compressed region differed significantly.

288

289   **The Poisson ratio of pyrope glass**

290

291   The Poisson ratio (σ) is shown as a function of pressure in Fig. 10. The Poisson ratio is

292   obtained directly from the measured elastic wave velocities by Equation (4).

Revision 2

$$\sigma = \frac{V_P^2 - 2V_S^2}{2(V_P^2 - V_S^2)}.$$ (4)

293   The Poisson ratio in depolymerized glasses is close to 0.3 at ambient pressure and seems to

294   increase monotonically (Sakamaki et al. 2014). The Poisson ratio in fully polymerized glasses is

295   ~0.2 under ambient conditions, although it increases rapidly with pressure (Sakamaki et al.

296   2014). The dependence of the Poisson ratio in pyrope glass on pressure was similar to that

297   observed in depolymerized glasses. Although the error is large, there may be an anomalous

298   behavior at pressures between 6 GPa and 9 GPa. A dramatic drop in the Poisson ratio indicated

299   that the volume of the glass decreased significantly.

300

301   **Compression behavior of pyrope glass**

302

303   Based on our structural measurements, we identified three pressure regions in which

304   structural changes were induced. Moderate structural changes characterized by a monotonous

305   shift in the FSDP position to higher Q values were observed at pressures at or below ~6 GPa.

306   The dependence of the FSDP position in $S(Q)$ on pressure changed at pressures between 6 and 9

307   GPa, and the T–T bond length and T–O–T angle in $g(r)$ both decreased. At pressures at or above

308   9 GPa, the T–O bond length increased. In the lower pressure range from 1 atm to ~6 GPa, there

309   was an inverse relationship between the elastic wave velocity in the pyrope glass and pressure.

310   Moderate shrinkage of the IRO structure was observed, while the short-range structure was less

311   sensitive to pressure. Non-elastic deformation dominated the first stage of compaction. In the

312   mid-pressure range (6–9 GPa), shrinkage of the IRO structure in the pyrope glass was fairly

313   significant. The dependence of the elastic properties on pressure became positive. The structure

314   of the glass became more compact due to topological rearrangement associated with a decrease

Revision 2

315 in the T–O–T angle. A change in the compaction mechanism may have been related to changes in

316 the pyrope melting curve near 7 GPa (Irifune and Ohtani 1986; Zhang and Herzberg 1994). In

317 the high-pressure range ($\geq$9 GPa), pressure-induced changes in the elastic properties of the

318 pyrope glass and the FSDP position were moderate. First-principles molecular dynamics

319 simulations have revealed a relationship between the structure of anorthite ($CaAl_2Si_2O_8$) glass

320 and the velocity of sound waves (Ghosh and Karki 2018). Based on the results of that study, the

321 tetrahedral cations underwent primarily topological changes. These did not significantly affect

322 the average bond distance or coordination during the initial stages of cold compression (0–10

323 GPa). The velocity of sound waves began to increase sharply at pressures above ~10 GPa, and

324 the T–O bond length increased. Similar changes in velocity and structure have been observed in

325 SiO_2 glass at pressures in the range of 15–20 GPa (Zha et al. 1994; Benmore et al. 2010). A

326 structural analysis of SiO_2 glass also indicated that the dependence of the Si–O bond length on

327 pressure changed from negative to positive, and the Si–O CN increased at the same pressures

328 (Benmore et al. 2010). The relationship between sound wave velocity and the T–O bond length

329 may be a common feature in silicate glasses, although the changes occur at different pressures

330 due to variations in chemical composition. The onset of such increases is particularly affected by

331 the presence or absence of aluminum.

332

Implications

334 In this study, we demonstrated that the structural densification of pyrope glass was

335 closely related to changes in its elastic properties. The compression behavior of pyrope glass was

336 distinctly different in three pressure regions. Moderate shrinkage of the IRO was observed at

337 pressures below GPa. IRO shrinkage was relatively pronounced at pressures in the range from 6

Revision 2

338   GPa to 9 GPa. The T–O CN increased at pressures above 9 GPa. Compared to other silicate

339   glasses, the chemical composition of pyrope glass had a more significant effect on its properties

340   and pressure dependence (Figs. 6–8). Although pyrope, diopside, and enstatite were all

341   magnesium-bearing silicate glasses with velocities that had similar absolute values at low

342   experimental pressures, the velocity in pyrope glass was highest at higher pressures. This was

343   due to densification related to the presence of Al. Magnesium is abundant in the partially melted

344   regions of the Earth's mantle, particularly in the deeper regions (Nakajima et al. 2019). Al-

345   bearing hydrous minerals are stable in the lower mantle (Xu and Inoue 2019). Hydrous minerals

346   have an important role in mantle melting, because they become sources of H_2O in the lower

347   mantle when they are dehydrated. Partial melts that form in the deep mantle are rich in

348   magnesium and aluminum, which are incorporated into the melt. Therefore, knowledge about

349   magnesium-bearing aluminosilicate glass can further our understanding of deep magma

350   behavior.
