14

15   **Abstract**

16   To clarify the effect of water on carbonate-silicate liquid immiscibility in the diamond

17   stability field, we performed experiments in the system KAlSi$_3$O$_8$-CaMgSi$_2$O$_6$-NaAlSi$_2$O$_6$-

18   CaMg(CO$_3$)$_2$ under nominally dry and hydrous conditions with adding 1.5 wt% H$_2$O at a

19   pressure of 6 GPa and temperatures of 1000 to 1500 °C. Both systems start to melt at 1050-1100

20   °C. Under anhydrous condition the melting occurs via the following reaction: 6KAlSi$_3$O$_8$ (K-

21   feldspar) + 6CaMg(CO$_3$)$_2$ (dolomite) = 2(Ca$_n$,Mg$_{1-n}$)$_3$Al$_2$Si$_3$O$_{12}$ (garnet) + Al$_2$SiO$_5$ (kyanite) +

22   11SiO$_2$ (coesite) + 3K$_2$(Ca$_{1-n}$,Mg$_n$)$_2$(CO$_3$)$_3$ (carbonatitic melt) + 3CO$_2$ (fluid and/or liquid),

23   where n ~ 0.3−0.4. The carbonatitic melt has the following composition

24   38(K$_{0.92}$Na$_{0.08}$)$_2$CO$_3$·62Ca$_{0.62}$Mg$_{0.38}$CO$_3$. A second immiscible silicic melt containing (in wt%,

25   volatile free) SiO$_2$ = 68.8, Al$_2$O$_3$ = 12.6, CaO = 3.7, MgO = 2.4, Na$_2$O = 1.1, K$_2$O = 11.3 appears

1

26   at 1250 °C. Both melts remain stable up to 1500 °C and coexist with the clinopyroxene ± garnet

27   ± coesite residue assemblage. In the presence of water stored away in phengite, the melting

28   begins from silicic melt, which contains (in wt%, volatile free) $SiO_2 = 61.4$, $Al_2O_3 = 15.3$, CaO =

29   4.8, MgO = 3.0, $Na_2O = 2.2$, $K_2O = 13.3$ and coexists with phengite, dolomite, clinopyroxene,

30   and coesite. The phengite + dolomite assemblage remains to 1100 °C and disappears at 1200 °C

31   producing two immiscible melts carbonatitic with approximate composition,

32     $19(K_{0.89}Na_{0.11})_2CO_3 \cdot 81Ca_{0.57}Mg_{0.43}CO_3$, and silicic containing (in wt%, volatile free) $SiO_2 =$

33   63.3, $Al_2O_3 = 15.6$, CaO = 4.5, MgO = 3.0, $Na_2O = 2.0$, $K_2O = 11.6$. The present results imply,

34   that partial melting of continental material subducted to a depth of 200 km can yield

35   simultaneous formation of two immiscible melts, K-dolomitic and K-aluminosilicate. Under dry

36   conditions, carbonatitic melt appears earlier (at a lower temperature). Given the low density and

37   high mobility of this melt, it must quickly percolate upward, leaving a refractory eclogite-like

38   residue and leaving no chance for the formation of a second aluminosilicate melt. However,

39   under hydrous conditions silicate melt appears earlier than carbonatitic melt, leaving a phengite-

40   and dolomite-bearing residue, which finally yields the formation of two immiscible silicic and

41   carbonatitic melts. The compositions of these melts fall in the compositional range of

42   carbonatitic and silicic HDFs in diamonds worldwide. Thus, we suggest that the presence of

43   water is a necessary requirement for the formation of immiscible HDFs inclusions in diamonds

44   and this suggestion is strongly supported by natural data from HDFs.

45

47   high-density fluids, diamond formation, high-pressure experiment, Earth's upper mantle.

48

49   **Introduction**

50   Compositions of inclusions in diamonds from kimberlites worldwide indicate that highly-

51   potassic carbonatitic and silicic melts/fluids, so-called high-density fluids (HDFs), have existed

52   at the base of the continental lithosphere during the most of the Earth's history (Smith et al.

53   2012; Shirey et al. 2013). HDFs are believed to be responsible for mantle metasomatism and the

54   formation of the lithospheric diamonds (Navon et al. 1988). Unlike peridotite- or eclogite-

55   derived melts (Yaxley and Brey 2004; Dasgupta and Hirschmann 2007; Brey et al. 2008), HDFs

56   are characterized by abnormally high concentrations of alkalis, especially potassium (Bulanova

57   et al. 1988; Navon et al. 1988; Novgorodov et al. 1990; Schrauder and Navon 1994).

58   It was recently found that potassic aluminosilicate and potassic-dolomitic melts, similar to

59   silicic and carbonatitic HDFs in diamonds, are immiscible and can be formed by partial melting

60   of carbonated pelites at 6 GPa (Shatskiy et al. 2019). However, the anhydrous pelite melting

61   begins from a potassic-dolomitic melt at 1000 °C whereas a potassic aluminosilicate melt

62   appears 200 °C higher. It is well known that carbonatite melt is very mobile owing to its

63   buoyancy, low viscosity, and excellent wetting properties (Minarik and Watson 1995; Dobson et

64   al. 1996; Hammouda and Laporte 2000; Stagno et al. 2018). Consequently, it must rapidly

65   escape from the subduction plate leaving a K- and volatile-poor eclogite-like residue and

66   therefore leaving no chance for the formation of a silicic melt. Yet, the experiments of Shatskiy

67   et al. (2019) were conducted under nominally anhydrous conditions and therefore leave obscure

68   the role of water. Water is an important component of the silicic HDF, which may extend the

69   stability of the silicic melt to lower temperatures. It was recently found that hydrous silicic fluid

70   constituted by H_4SiO_4 and $H_6Si_2O_7$ (which could have a composition much more complex, with

71   presence of Na+, K+, Ca^{2+}, and Mg^{2+}) is present as submicron films around most typical mineral

72   inclusions in gem-quality diamonds from kimberlites worldwide (Nimis et al. 2016; Nestola et

73   al. 2018; Nestola et al. 2019a; Nestola et al. 2019b). It is therefore interesting to study a principal

74   effect of water on phase relations and liquid immiscibility in the systems modeling phase

75   relations in carbonated pelites at 6 GPa.

76   Here we present an experimental study of the subsolidus and melting phase relations in the

77   system $KAlSi_3O_8$ + $CaMgSi_2O_6$ + $NaAlSi_2O_6$ + $CaMg(CO_3)_2$ (Kfs + Di + Jd + Dol) under

78   nominally 'dry' and hydrous conditions at 6 GPa and 900−1500 °C.

79

80   **Experimental techniques**

81   *General procedures*

82   All experiments were performed using the 'Discoverer-1500' DIA-type press and a Kawai-

83   type inner stage of anvils at IGM SB RAS in Novosibirsk, Russia. The inner stage consists of

84   eight 26-mm tungsten carbide cubes, "Fujilloy N-05", with 12-mm truncations. ZrO_2 pressure

85   media (OZ-8C, MinoYogyo Co., Ltd (Shatskiy et al. 2010)) were shaped as a 20.5 mm

86   octahedron with ground edges and corners. Pyrophyllite gaskets, 4.0 mm in both width and

87   thickness, were used to seal the compressed volume and support the anvil flanks.

88   The cell assembly allows simultaneous loading up to 16 cylindrical samples of 0.9 mm in

89   both diameter and height in a single run (Shatskiy et al. 2018). The sample temperature was

90   measured by a $W_{97}Re_3$-$W_{75}Re_{25}$ thermocouple and controlled automatically within 2.0 °C of the

91   desired value. No correction of the effect of pressure on emf was applied. The maximum

92   temperature gradients within the sample charge were estimated to be from 5 to 8 °C/mm as

93   temperature increases from 1000 to 1500 °C, respectively (Shatskiy et al. 2013). High-

94   temperature pressure calibration was carried out using known phase transitions in SiO_2 (quartz-

95   coesite) (Hemingway et al. 1998) and in $CaGeO_3$ (garnet-perovskite) (Ono et al. 2011).

96   Uncertainty in the temperature and pressure is less than 20 °C and 0.5 GPa, respectively

97   (Shatskiy et al. 2018).

98   *Starting materials*

99   Reagent grade oxides, carbonates, $Ca(OH)_2$, and natural magnesite (<0.1% impurity) and

100   dolomite (<0.3% impurity) from Brumado (Bahia, Brazil), synthetic $NaAlSi_2O_6$ and $CaMgSi_2O_6$

101   glasses, and synthetic $CaSiO_3$ wollastonite were used to prepare starting mixtures. The starting

4

102   materials were blended in an agate mortar with acetone and loaded as a powder into graphite

103   capsules. The loaded capsules were dried at 300 °C for 1–2 h. Prepared assemblies were stored at

104   200 °C in a vacuum for ≥12 h prior to the experiment. All experiments were conducted at 15-35

105   % indoor humidity.

106   ***Preparation of experimental samples***

107   Since the samples are highly hygroscopic, their preparation requires special care. To avoid

108   the sample damage by atmospheric humidity, we minimized the residence time of the samples on

109   air and used anhydrous lubricants to polish them like that reported by Arefiev et al. (2019a) and

110   Shatskiy et al. (2019).

111   ***Analytical procedures***

112   Recovered samples were studied using a MIRA 3 LMU scanning electron microscope

113   (Tescan Orsay Holding) coupled with an INCA energy-dispersive X-ray microanalysis system

114   450 equipped with the liquid nitrogen-free Large area EDS X-Max-80 Silicon Drift Detector

115   (Oxford Instruments Nanoanalysis Ltd) at IGM SB RAS (Lavrent'ev et al. 2015). Energy-

116   dispersive X-ray (EDX) spectra were collected by using an electron beam-rastering method, in

117   which the stage is stationary while the electron beam moves over the surface area, with

118   dimensions 5-50 μm (for mineral phases) and 50-500 μm (for a quenched melt) at 20 kV

119   accelerating voltage and 1.5 nA beam current. Live counting time for X-ray spectra was 20 s. In

120   the case of low-contrast buck scattered electron (BSE) images, we used element mapping mode

121   combining X-ray intensities of the selected elements (up to three).

122   Raman measurements were performed using a Horiba Jobin Yvon LabRAM HR800

123   Raman microspectrometer with the 532-nm Nd:YAG solid-state laser at IGM SB RAS. Spectra

124   were recorded at ambient conditions in backscattering geometry with a laser power of about 1

125   mW and a spectral resolution of approximately 2 cm^{-1}.

126

127   **Experimental results**

5

128   ***The system $KAlSi_3O_8 + CaMgSi_2O_6 + NaAlSi_2O_6 + CaMg(CO_3)_2$***

129   The results of the experiments are summarized in Table S1. The mass balance calculations

130   are given in Table S2 in mol% and Table S3 in wt%. The compositions of melts, clinopyroxene,

131   and garnet are presented in Table S4. The BSE images of selected samples are shown in Fig. 1.

132   See the nomenclature section for abbreviations.

133   In run no. D070 (900 °C, 96 h), the sample consists mostly of unreacted components of the

134   starting mixture: $CaMg(CO_3)_2$ (Dol) + $CaMgSi_2O_6$ (Di) + $NaAlSi_2O_6$ (Jd) + $KAlSi_3O_8$ (Kfs). Kfs

135   is partially replaced by Wad + Ky + Coe.

136   The subsolidus assemblage established at 1000 °C (run no. D070, 96 h) is mainly

137   represented by Kfs, Cpx, and Dol (Figs. 1a, 2a, Tables S2, S3). The Kfs grains contain numerous

138   submicrometer inclusions of Al_2O_3-poor, SiO_2- and K_2O-rich phase, presumably Wad (Fig. 1a).

139   Kfs grains are surrounded by a three-phase aggregate of Wad, Ky and Coe (Fig. 1a). The small

140   grain size allows only semiquantitative analysis of phases in this run. Cpx is represented by the

141    $Di_{51}Jd_{38}En_3Ts_8$ solid solution and has slightly higher Ca# (52 mol%) than dolomite (Ca# = 48

142   mol%) (Fig. 3, Table S4).

143   At 1050 °C (run no. D026, 96 h), the LT sample side consists of the Cpx + Dol + Kfs +

144   Mgs aggregate, whereas the Cpx + Coe + Kfs + Ky + L(C) assemblage appears at the HT sample

145   side (Fig. 1b-d). The Cpx composition is $Di_{47}Jd_{41}En_4Ts_8$ (Fig. 3, Table S4). L(C) quenches to a

146   dendritic intergrowth of carbonates and appears in the interstitial space within the Cpx + Kfs +

147   Coe + Ky matrix (Fig. 1d). In molar proportions, an approximate composition of L(C) is

148    $38(K_{0.92}Na_{0.08})_2CO_3 \cdot 62Ca_{0.62}Mg_{0.38}CO_3$ + 3.1 mol% SiO_2 + 1.1 mol% Al_2O_3 (Fig. 4, Table S4).

149   As temperature increases to 1100 °C (run no. D078, 47 h), Kfs disappears, the Dol fraction

150   decreases, and the Mgs fraction slightly increases (Fig. 2a). The LT sample side consists of Cpx,

151   Coe, Dol, Mgs, and Ky (Fig. 1e, f), whereas the HT side contains Cpx, Coe, and L(C) (Fig. 1e,

152   g).

6

153   At 1150 °C (run no. D031, 48 h), Dol and Mgs are completely consumed by the melting

154   reaction and the L(C) fraction increased (Fig. 2a, Tables S2, S3). L(C) forms a separate pool

155   adjacent to the HT capsule side (Fig. 1h, i). Well-shaped Grt and Coe crystals appear at the

156   contact with the L(C) pool (Fig. 1h, i). Some Grt crystals are suspended in the melt (Fig. 1i). The

157   LT sample side consists of Cpx, Coe, Grt and a minor amount of Ky (Fig. 1h). Grt is represented

158   by the $Prp_{74}Grs_{26}$ solid solution (Fig. 5, Table S4). Mass balance calculations indicate the

159   formation of molecular CO_2 as melting begins (Fig. 2a, Tables S2, S3).

160   At 1250 °C (run no. D038, 25 h), the L(C) fraction slightly increases, whereas the fractions

161   of Cpx, Coe, and Grt decrease and Ky completely disappears (Fig. 2a). Besides, L(S), containing

162   (in wt%) 64 SiO_2, 12 Al_2O_3, 2 MgO, 4 CaO, 1 Na_2O, 11 K_2O, and 7 CO_2 (Table S4), appears in

163   the interstitial space within the Cpx matrix (Fig. 1j, k).

164   With further temperature increase to 1350 °C (run no. D027, 24 h) and 1500 °C (run no.

165   D028, 6 h), the fraction of L(S) increases, while the fractions of Cpx and L(C) decrease (Fig. 2a,

166   Tables S2, S3). L(S) forms a separate pool sandwiched by L(C) and residue phases (Fig. 1l-o).

167   The rounded blebs of L(C) can be also seen within the silicate glass and the Cpx ± (Grt + Coe)

168   matrix (Fig. 1l, m, o). Grt and Coe completely disappear at 1500 °C (Figs. 2a, 1n, o).

169   As temperature increases from 1050 to 1500 °C, the SiO_2 content in L(C) increases from 3

170   to 9 mol%, whereas K_2O decreases from 17 to 5 mol% (Fig. 4a, f, Table S4). The L(S)

171   composition reveals a decrease of the SiO_2 content and an increase of the MgO and CaO

172   contents as temperature increases from 1250 to 1500 °C (Fig. 4a, c, d, Table S4). Above the

173   solidus, the Jd content in Cpx changes insignificantly, while the amount of the En component in

174   Cpx increases (Fig. 3a, c, Table S4).

175

176   ***The system $KAlSi_3O_8 + CaMgSi_2O_6 + NaAlSi_2O_6 + CaMg(CO_3)_2 + H_2O$***

177   The results of the experiments including the run conditions and phase compositions in both

178   mol% and wt% are summarized in Table S5. The mass balance calculations are given in Table

7

179   S6 in mol% and Table S7 in wt%. The compositions of L(C), L(S), Cpx, and Grt are presented in

180   Table S8. The BSE images of selected samples are shown in Fig. 6.

181   At 900 °C (run no. D011, 71 h) and 1000 °C (run no. D016, 96 h), the subsolidus

182   assemblage consists of Cpx, Ph, Coe, and Dol (Figs. 2b, 6a, b, Table S5). Besides a minor

183   amount of Kfs was observed at 1000 °C (Figs. 6b).

184   The first melt appears at 1100 °C (run no. D015, 48 h) (Fig. 6c). The melt has an

185   aluminosilicate composition (Table S8). L(S) quenches to a glass, which fills interstitial space

186   between euhedral Cpx crystals (Fig. 6c). Coe, Ph, Dol, and Mgs were also established among the

187   run products (Fig. 6c, Table S5).

188   As temperature increases to 1200 °C, L(C) appears in addition to L(S) (Fig. 2b, 6d, e,

189   Table S5). L(C) forms a separate pool at the HT side, whereas L(S) fills interstitial space

190   between the Cpx crystals (Fig. 6d, e). The LT sample side is mainly represented by Cpx and Coe.

191   Mgs appears as a thin layer attached to the LT capsule end (Fig. 6d). Grt forms well-shaped

192   crystals up to 50 μm in size suspended in the L(C) (Fig. 6e). Besides, the quenched products of

193   L(C) contain graphite, which looks like numerous black worms on the BSE images (Fig. 6d, e).

194   The graphite was also observed in the quenched products of L(C) as separate crystals at 1300 °C

195   (Fig. 6f, g) and as their segregations at the interface with L(S) at 1400 °C (Fig. 6h, i).

196   At 1300 °C (run no. D013, 49 h), solid carbonates completely disappear and the residual

197   assemblage is represented by Cpx, Grt, and Coe (Figs. 2b, 6f, g). L(S) forms a pool at the HT

198   side, while L(C) appears as irregular-shaped and rounded bubbles within L(S) (Fig. 6f, g).
199   As temperature increases to 1400 °C (run no. D017, 8 h), the assemblage and the fractions

200   of phases remain the same (Fig. 2b, Tables S6, S7). L(C) forms a separate pool at the HT side.

201   The L(S) pool is adjacent to that of L(C) from the LT side (Fig. 6h, i). Both L(C) and L(S) also

202   appear in the interstitial space and small segregations between residual crystals of Cpx, Grt , and

203   Coe at the LT sample side (Fig. 6h, i).

8

204   As temperature increases over the entire temperature range, the Jd content in Cpx

205   decreases, the En and Ts contents increase, while the Di content does not change systematically

206   (Fig. 3). Ca# of Grt decreases as temperature increases (Fig. 5). The melts retain nearly constant

207   composition (Table S8). Among the obvious changes, an increase in the MgO and Na_2O contents

208   and a decrease in the K_2O content of L(C) can be noted (Table S8).

209

210   **Discussion**

211   According to the previous experimental results on phase relations in 'dry' carbonated

212   pelite, the generation of the first highly potassic dolomitic melt at 6-8 GPa is controlled by

213   melting reactions involving Ca-Mg carbonates (Dol or Arg+Mgs) and K-phases (Kfs or Wad)

214   (Grassi and Schmidt 2011a; Shatskiy et al. 2019). Based on the phase relations established here

215   in the Kfs + Di + Jd + Dol system (Fig. 2a, Table S2), the melting reaction can be approximated

216   as follows:

217    $6KAlSi_3O_8$ (Kfs) + $6CaMg(CO_3)_2$ (Dol) = $2(Ca_n,Mg_{1-n})_3Al_2Si_3O_{12}$ (Grt) + Al_2SiO_5 (Ky) +

218    $11SiO_2$ (Coe) + $3K_2(Ca_{1-n},Mg_n)_2(CO_3)_3$ (L) + $3CO_2$ (F and/or L),   (1)

219   where n ~ 0.3−0.4. Reaction 1 yields redistribution of potassium from K-feldspar to L(C) with

220   approximate composition $38(K_{0.92}Na_{0.08})_2CO_3·62Ca_{0.62}Mg_{0.38}CO_3$. The L(C) composition

221   resamples peritectic P[1] in the K_2CO_3-$CaCO_3$-$MgCO_3$ system established between 1050 and 1100

222   °C and controlled by the reaction $K_2Ca_3(CO_3)_4 + K_2Mg(CO_3)_2 \rightarrow MgCO_3$ + L(C) (Fig. 7)

223   (Arefiev et al. 2019b).

224   The established phase relations (Fig. 2b, Table S6) suggest that clinopyroxene does not

225   play a decisive role in the incipient melting. Similar phase relationships and L(C) compositions

226   in the systems Kfs + Di + Jd + Dol and carbonated pelite (DG2) at 6 GPa (Shatskiy et al. 2019)

227   (Figs. 2b, f, 4) indicate that reaction 1 is dominant melting reaction controlling the solidus of the

228   'dry' carbonated pelite at 6 GPa.

9

229   Adding water to the Kfs + Di + Jd + Dol system stabilizes phengite with the expense of K-

230   feldspar (Fig. 2). As temperature increases from 1000 to 1100 °C the phengite fraction decreases

231   by nearly half, which accompanies an appearance of L(S) and increasing the coesite fraction

232   (Fig. 2b). Our observation is in good agreement with the results of Domanik and Holloway

233   (1996) which indicate that phengite melting occurs near 1100 °C at 6 GPa in a pure mica system.

234   Our data are also consistent with the results of Thomsen and Schmidt (2008) who observed the

235   disappearance of phengite and appearance of L(S) at 1100 °C in the system pelite-CO_2-H_2O at 5

236   GPa. Unlike Thomsen and Schmidt (2008), who observed the disappearance of Ca-Mg carbonate

237   and appearance of immiscible L(C) at 1100 °C, in our study dolomite and phengite retain up to

238   1100 °C and disappear at 1200 °C yielding an appearance of L(C) (Fig. 2a).

239   Thus, in presence of water, L(S) can appear even earlier then L(C). L(S) contains (in wt%,

240   volatile free) $SiO_2 = 61.4$, $Al_2O_3 = 15.3$, $CaO = 4.8$, $MgO = 3.0$, $Na_2O = 2.2$, $K_2O = 13.3$ (Table

241   S8) and resembles L(S) coexisting with L(C) in the system pelite-CO_2-H_2O at 5 GPa and 1050-

242   1100 °C (Thomsen and Schmidt 2008; Tsuno et al. 2012) (Table S9).

243   The composition of immiscible L(C), $21(K_{0.93}Na_{0.07})_2CO_3 \cdot 79Ca_{0.59}Mg_{0.41}CO_3$, resembles

244   that established in equilibrium with L(S) under anhydrous conditions here and in 'dry'

245   carbonated pelite (DG2) system (Shatskiy et al. 2019) (Fig. 4). However, this L(C) is more

246   alkali-rich than that established by Tsuno et al. (2012) in coexistence with L(S) in the pelite-

247   CO_2-H_2O system at 5 GPa and 1050-1100 °C and containing 2-3 mol% $(K, Na)_2CO_3$ (Table S9).

248   Summarizing all available data on L(C) established in the system pelite-CO_2-H_2O at 5-8

249   GPa and 1000-1100 °C, we can suggest that the measured L(C) compositions are largely

250   scattered in terms of the $(K,Na)_2CO_3$ content, which varies from 2-3 mol% to 26-36 mol%

251   (Table S9) (Thomsen and Schmidt 2008; Grassi and Schmidt 2011b; Grassi and Schmidt 2011a;

252   Tsuno et al. 2012). Such large variations inside the 100 °C temperature range are more likely

253   associated with the analytical problems rather than reflect the actual compositions of the melts.

10

254   Deviation of the composition of L(C) towards low alkalinity can be caused by the

255   following reasons. Carbonate specimens containing K_2CO_3 and Na_2CO_3 are highly hygroscopic

256   and can be easily damaged by atmospheric humidity. Therefore, some alkalis can be lost during

257   sample preparation and polishing. Another reason is the poor stability (evaporation) of alkaline

258   carbonates under a focused electron beam during EPMA analysis (Shatskiy et al. 2017; Arefiev

259   et al. 2019a; Shatskiy et al. 2019).

260   Incipient melting of carbonated pelite yields L(S) at $\leq$ 5 GPa and L(C) at $\geq$ 5 GPa

261   (Thomsen and Schmidt 2008; Grassi and Schmidt 2011b; Tsuno et al. 2012). Heating of

262   carbonated pelite (DG2) at 6 GPa under anhydrous conditions to 1200 ° C, which is 200 ° C

263   above its solidus, is accompanied by the formation of L(S) coexisting with L(C) to at least 1500

264   °C (Shatskiy et al. 2019) (Fig. 2f). The present results show that the anhydrous analog system

265   Kfs + Di + Jd + Dol behaves in a similar manner (Fig. 2a).

266   Adding water to this system in an amount slightly less than that required to complete

267   replacement of K-feldspar by phengite lowers the melting temperature of silicate component

268   yielding an appearance of L(S) at 1100 °C (Fig. 2e). The incipient melting does not cause the

269   complete consumption of K-phase and carbonate. The most of phengite and dolomite remains in

270   the residue and disappear only at 1200 °C to produce two immiscible melts, L(S) and L(C) (Fig.

271   2b, Tables S6, S7). These melts remain stable to at least 1400 °C in coexistence with the Cpx +

272   Grt + Coe residual assemblage. The present results suggest that the immiscibility gap between

273   potassic aluminosilicate and potassic-dolomitic melts does not be affected by a moderate amount

274   of water (Fig. 8a). This immiscibility gap prevents the continuous transition from silicic to

275   carbonatitic melt through fractional crystallization over any reasonable range of geothermal

276   conditions.

277   Figure 8 illustrates the compositions of the melts obtained in the present study (pink and

278   blue rhombuses, L(S), and circles, L(C)) in comparison with the pelite-derived melts (grey

279   symbols) and inclusions of HDFs in diamonds worldwide (small colored open circles) (see

11

280   Shatskiy et al., 2019 and references therein). The obtained L(S) in the present study resembles

281   pelite-derived phonolitic to trachytic melts (Fig. 4) and fall in the compositional range of the

282   silicic HDFs (brown open circles in Fig. 8a). The established L(C) resembles 'low-Mg' (Ca# 40–

283   70) carbonatite inclusions in 'fibrous' diamonds from the Ebelyakh placers of the northeastern

284   Siberian craton (Zedgenizov et al. 2011) and some other localities (e.g., (Logvinova et al. 2019)).

285   However, most carbonatitic HDFs belongs to 'high-Mg' (Ca# 10-40) (green open circles in Fig.

286   8b) (Klein-BenDavid et al. 2009; Weiss et al. 2009; Zedgenizov et al. 2009). Sokol et al. (2017)

287   found that interaction of pelite-derived 'low-Mg' L(C) with harzburgite at 1200 and 1350 °C

288   yields the wehrlitization reaction, which shifts the L(C) composition from 'low-Mg' to 'high-

289   Mg'.

290

291   **Implications**

292   The composition of melt inclusions in natural diamonds varies from silicic (phonolite-

293   trachyte) to carbonatitic (K-dolomite) (Bulanova et al. 1988; Navon et al. 1988; Novgorodov et

294   al. 1990; Schrauder and Navon 1994). Our results indicate that the silicic and carbonatitic

295   endmembers are immiscible and can be derived by partial melting of the phengite ± K-feldspar +

296   clinopyroxene + dolomite assemblage at 6 GPa above 1100 °C. The immiscibility between

297   coexisting carbonatitic and silicic melts explains the fractionation of Nb from Ta, or Zr from Hf

298   observed in the trace-element patterns of fibrous and monocrystalline diamonds (Rege et al.

299   2010). Our results show that water stored away in phengite has a strong influence on the

300   temperature stability of silicic melt, while it does not affect solidus temperature. The presence of

301   water lowers melting temperatures of aluminosilicate components expanding the stability field of

302   silicic melt toward the lower temperature of ≤ 1100 °C. Thus, the immersion of carbonated

303   material of the continental crust into the mantle by subduction slabs or by continental collision

304   could yield simultaneous formation of phonolite-trachytic and K-dolomitic immiscible melts

305   responsible for the formation of lithospheric diamonds.

12

306

Nomenclature

Coe – coesite, Cpx – clinopyroxene, Di – diopside, Dol – dolomite, En – enstatite, F – CO_2 fluid, Grs – grossular, Grt – garnet, Jd – jadeite, Wad – wadeite structured $K_2Si_4O_9$, Kfs – K-feldspar, Ky – kyanite, L(S) – silicic melt, L(C) – carbonatitic melt, Mgs – magnesite, Ph – phengite, Prp – pyrope, Ts - $CaAlSiAlO_6$ tschermakite.
