ABSTRACT

Aluminum-rich and Si-poor calcium amphibole [~3.9 Al atom per formula unit (apfu)

and ~5.5 Si apfu for 23 O] occurs in the quartz-bearing eclogites from the Donghai area,

Sulu ultrahigh-pressure metamorphic belt, eastern China. Most of the aluminous

25   amphibole phases are retrograde products from the exhumation and hydration stage, and

26   are texturally divided into a mantle phase around a porphyroblastic garnet and

27   crack-filling (vein) phase of a garnet. Less aluminous amphibole occurs as symplectite

28   phase with plagioclase after omphacite. The formation process of the aluminous

29   amphibole in the quartz-bearing samples is discussed on the basis of the analytical data

30   by EPMA, FIB-TEM, and EBSD.

31   The mantle amphibole occurs between garnet and symplectite or quartz. A set of

32   plagioclase and aegirine-diopside/argirine-hedenbergite thin monomineralic bands forms

33   at the boundary between the mantle amphibole and matrix quartz. However, these

34   monomineralic bands do not occur at the mantle amphibole-symplectite boundary. These

35   textural differences indicate that the recrystallization of the aluminous amphibole around

36   garnet was controlled by significant local reactions and the size of equilibrate domains

37   were probably several tens of micrometers or less.

38   The mantle amphibole is composed of inner (garnet-side) and outer (matrix-side)

39   zones. The inner zone is compositionally homogeneous and its atomic Al/Si value is

40   approximately 0.63–0.66, and similar to that of garnet. Atomic Ca/Si value in the inner

41   zone is also almost uniform, and is generally identical to that of garnet. The outer zone

42   exhibits a monotonic decrease in the Al/Si and Ca/Si values outwards, and its

43   composition at the outermost margin is similar to that of the symplectitic amphibole.

44   The crack-filling amphibole has a composition similar to the inner zone of the mantle

45   amphibole. The CPO pattern of the crack-filling amphibole is different from that of the

46   adjacent mantle amphibole, showing that the crack-filling amphibole is cut by the mantle

47   amphibole. The textural relationship between the mantle and crack-filling amphibole

48   phases and their compositional characteristics imply that (1) the mantle type is a slightly

Enami and others

49   later stage product than the crack-filling type and (2) the boundary between the inner

50   and outer zones of the mantle aluminous amphibole probably corresponds to the initial

51   surface of the porphyroblastic garnet. The inner zone is considered to have grown

52   inward by simple substitution of garnet, using the tetrahedral and octahedral cations of

53   the garnet as the basic framework. On the other hand, most of the outer zone of the

54   mantle-type amphibole grew outwards in the matrix from the initial surface of the

55   garnet porphyroblast. The mantle amphibole shows a CPO similar to that of amphibole

56   in the adjacent symplectite domain, suggesting that these two types of amphibole

57   formed almost simultaneously, sharing crystallographic orientation with each other.

58   The formation of crack-filling aluminous amphibole was probably promoted by the

59   hydraulic microfracturing process at an early stage of exhumation and hydration. The

60   mantle and symplectitic amphibole phases formation was promoted by the subsequent

61   infiltration of metamorphic fluid. The aluminous amphibole in the SiO_2 phase-bearing

62   eclogites probably recrystallized with the formation of a localized SiO_2-undersaturated

63   reaction domain because of rapid exhumation and subsequent rapid cooling of the Sulu

64   UHP metamorphic belt.

65

66   **Keywords**: Aluminous amphibole, EPMA, FIB-TEM, EBSD, eclogite, Sulu UHP

67   metamorphic belt

68   **INTRODUCTION**

69   Detailed compilations of the chemical compositions of amphibole formed under

70   various environmental conditions show that most of the calcium amphibole phases are

71   more siliceous and/or less aluminous than the tschermakite–pargasite solid solution (e.g.,

72   Deer et al., 1997; Martin, 2007; Schumacher, 2007). An aluminous [~4.5 atom per

2

Enami and others

73 formula unit (apfu) for 23O) and Si-poor (~4.6 apfu) calcium amphibole, a sadanagaite,

74 was first reported from spinel-bearing skarns in the Ryoke low pressure (P)/temperature

75 (T) metamorphic belt, Japan, by Shimazaki et al. (1984). Subsequently, the aluminous

76 and Si-poor amphibole, which is hereafter defined as aluminous amphibole unless

77 otherwise stated, has been described from various types of lithologies. They have mostly

78 SiO_2-depleted whole-rock compositions such as metacarbonate (Mogessie et al., 1986),

79 the reaction zone between the crystalline limestone and K-metasomatized basalt in

80 granitic contact aureole (Sawaki, 1989), calc-silicate pods in layered gneisses of the

81 transitional amphibolite and granulite facies conditions (Shiraishi et al., 1994),

82 corundum- and spinel-bearing schist (Savel'eva and Korikovskii, 1998), and

83 K-metasomatized basalt around granite intrusions (Banno et al., 2004). Appleyard (1975)

84 also reported aluminous amphibole (~3.3 Al apfu and ~5.3 Si apfu) from spinel-bearing

85 metasomatic alkaline gneisses before the application for registration and its acceptance

86 as a new mineral, "sadanagaite". The extent of tschermak substitution in calcic

87 amphibole is sensitive to silica activity (e.g., Hoschek, 1995), and these limited

88 occurrences of aluminous calcium amphibole could indicate that the SiO_2-undersaturated

89 system generally plays a definitive role in the formation of aluminous amphibole.

90   However, Si-poor and aluminous amphibole phases (~3.5–3.7 Al apfu and ~5.8–5.5 Si

91 apfu) have been occasionally reported from retrograde eclogites in Alps (e.g., Mogessie

92 et al., 1986; Messiga et al., 1991; Poli, 1991) and Himalaya (e.g., Palin et al., 2014;

93 O'Brien, 2019). They sometimes occur as pseudomorphs after garnet also in coesite

94 eclogites from several localities of the Sulu ultrahigh-pressure (UHP) metamorphic belt,

95 China, such as Rongcheng, Yangkou, and Donghai areas (~3.5 Al apfu and ~5.5 Si apfu:

96 Enami et al., 1993; Yang, 2004; Liu et al., 2009; Yamasaki et al., 2018). Yang (2004)

Enami and others

97 discussed the mass transfer during the formation of retrograde amphibole grains using

98 the isocon method. However, it has not been well understood why these aluminous

99 amphibole phases recrystallized in the SiO_2-excess whole-rock compositions.

100 In this study, we focused on the fact that aluminous amphibole phases, which coexist

101 with coesite/quartz, characteristically occur in eclogites, and systematically analyzed the

102 aluminous amphibole phases in coesite eclogites from the Donghai area of the Sulu UHP

103 metamorphic belt as a case study. We will describe the mode of occurrence,

104 compositional characteristics, and relationships of crystallographic orientations of the

105 aluminous amphibole based on the analytical results of electron probe microanalyzer

106 (EPMA), focused ion beam system (FIB)-transmission electron microscope (TEM), and

107 electron back scattered diffraction (EBSD) method, and then discuss the cause of the

108 formation of aluminous amphibole in SiO_2-saturated rocks.

109

110 **GEOLOGICAL SETTING AND PETROGRAPHY**

111 Samples studied were collected from Qinglongshan (JDQ03) and Caihu (91CHXX

112 and 91CH08) areas in the Donghai region, which is located at the southwestern part of

113 the Sulu UHP metamorphic belt, eastern China (Fig. 1). Geological map of the

114 Qinglongshan area was reported by Yang (2004). Eclogites (e.g., Zhang et al., 1995;

115 Nagasaki and Enami, 1998), ultramafic and related rocks (e.g., Enami and Zang, 1988;

116 Zhang et al., 2004, 2008, 2011), and their host orthogneiss and paragneiss occur

117 extensively in the Donghai area (Fig. 1b). Hirajima et al. (1990) described a coesite

118 eclogite from Mengzhong, which was one of the first reports of authentic evidence for

119 UHP metamorphism in the Sulu UHP metamorphic belt (Fig. 1b). Many petrological

120 and mineralogical studies have been conducted also on core samples from the Chinese

4

Enami and others

121   Continental Scientific Drilling (CCSD) main drill hole (e.g., Liu et al., 2001; Zhang et

122   al., 2006).

123   Common occurrences of coesite and other UHP index phases indicate that the eclogite,

124   ultramafic rock, and their host gneisses in the Donghai area were extensively

125   recrystallized under the coesite eclogite facies conditions (e.g., Zhang et al., 2005, 2009;

126   Liu and Liou, 2011). Peak metamorphic conditions for the Donghai area were estimated

127   at 2.2–4.0 GPa/620–880 °C (e.g., Zhang et al., 2000; Li et al., 2011; Yamasaki et al.,

128   2018). Yamasaki et al. (2018) systematically studied amphibole-bearing samples from

129   Qinglongshan and Jianchang (Fig. 1b) and concluded that sodium-calcium amphibole

130   phases (barroisite–taramite) have been stable under UHP metamorphic stage. The

131   eclogites in the Donghai area are considered to have experienced near isothermal

132   decompression down to amphibolite or lower-granulite facies conditions during early

133   exhumation (e.g., Enami et al., 1993; Zhang et al., 1995). Mafic phases of the eclogite

134   facies stage were replaced to varying degrees by amphibole and other phases because of

135   hydration reactions undergone during this stage.

136   Petrographical characteristics of the sample JDQ03 were briefly described by Enami et

137   al. (1993). The present study was conducted on a newly prepared thin section, which

138   contains garnet, amphibole, epidote, phengite, and quartz (former coesite) as the main

139   coesite eclogite facies phases (Fig. 2a). Omphacite grains were completely recrystallized

140   to a symplectitic fine aggregate of sodic diopside, amphibole, and plagioclase. The

141   amphibole of the UHP metamorphic stage was confirmed to occur as inclusions in garnet

142   and matrix phase. Retrogressive amphibole was observed as a zone around garnet

143   (denoted as mantle amphibole hereafter, unless otherwise stated) and symplectitic

144   particles with sodic diopside and plagioclase after omphacite. The segment of mantle

Enami and others

145   amphibole is composed of a single phase and does not include any other phases. Rutile

146   and apatite are minor constituents, and K-feldspar occurs as an inclusion in garnet. Biotite

147   occurs as a retrograde phase replacing phengite.

148   The samples 91CHXX and 91CH08 are petrographically similar to each other. They

149   are mainly composed of garnet, amphibole, zoisite/epidote, paragonite, and quartz

150   (former coesite), with accessory minerals rutile and apatite. Omphacite occurs as

151   inclusions in garnet of 91CH08, and matrix omphacite grains of 91CHXX and 91CH08

152   were completely replaced by symplectite of sodic diopside, plagioclase, and amphibole

153   (Fig. 2b-d). In 91CHXX, amphibole of the eclogite facies stage was confirmed as an

154   inclusion in garnet and in an isolated matrix phase. Retrograde amphibole occurs as

155   crack-filling (vein) phase of garnet other than the mantle and symplectite amphibole

156   phases. The mantle and crack-filling amphibole phases in 91CHXX are a single phase

157   similar to the mantle amphibole in JDQ03 and do not contain any other phases. On the

158   other hand, the mantle and crack-filling amphibole phases in 91CH08 contain

159   fined-grained garnet (less than 25 μm in size).

160

161   **ANALYTICAL PROCEDURES**

162   The mineral compositions were analyzed using an EPMA with wavelength-dispersive

163   system (WDS, JXA-8900R; JEOL) at the Petrology Laboratory of Nagoya University.

164   The operating conditions were 15 kV accelerating voltage, 12 nA beam current, and a 2–3

165   μm beam spot diameter. Well-characterized natural and synthetic phases, including

166   synthetic F-phlogopite (F = 8.7 wt%) and natural Cl-rich hastingsite (Cl = 3.27 wt%,

167   Suwa et al. 1987), were employed as standards. Detection limits (2σ level) of F and Cl are

168   0.03 wt% and 0.01 wt%, respectively. The correction factors calculated by Kato (2005)

169   were employed for the matrix correction. Representative analyses of amphibole are

170   presented in Table 1. Minerals and endmember abbreviations are from Whitney and

171   Evans (2010), unless otherwise noted.

172   An ultra-thin section across a garnet–amphibole boundary was made using a FIB

173   system (Helios NanoLab G3 CX, ThermoFisher Scientific) at the Mineralogical

174   Laboratory of Kyoto University. A predefined area (~30 μm^2) was coated with platinum

175   (Pt) and its surround was cut out to a depth of 15 μm using a gallium (Ga) ion beam. Next,

176   the resulting foil was picked up by an *in-situ* tungsten (W)-probe inside the FIB and

177   mounted on a copper (Cu) TEM grid. The extracted sample was thinned to 200 nm using

178   a Ga ion beam at 30 kV with beam currents ranging from 0.1–3 nA and at 5 kV with a

179   beam current of 16 pA for the final processing. The TEM foil was examined at Kyoto

180   University using a TEM (JEM-2100F, JEOL) equipped with an energy-dispersive X-ray

181   spectroscopy (EDS) system (JED-2300T, JEOL) operating at 200 kV. The TEM images

182   were recorded using a charge-coupled device (CCD) camera (Orius200D, Gatan,

183   Pleasanton, CA, USA). The zone axes of individual amphibole and garnet grains were

184   identified based on selected area electron diffraction (SAED) patterns, which were

185   analyzed using a Gatan Digital Micrograph (GMS 3) and the ReciPro software

186   (http://pmsl.planet.sci.kobe-u.ac.jp/~seto/).

187   Crystal–preferred orientations (CPO) of minerals were measured by indexing EBSD

188   patterns produced in a Hitachi S–3400 N scanning electron microscope equipped with

189   an Oxford AZtec EBSD system at the Petrology Laboratory of Nagoya University.

190   Diffraction pattern acquisition was performed using an acceleration voltage of 20 kV

191   and a working distance of 27 mm. Processing and indexation of Kikuchi bands and

192   post-acquisition processing of crystallographic orientation measurements were made

Enami and others

193   using HKL Channel 5 software (Oxford Instruments). Pole figures were prepared using

194   PFctf and ROTctf4 computer programs by D. Mainprice and Matlab MTEX toolbox by

195   K. Michibayashi.

196

197   **MINERALOGY**

198   **Amphibole**

199   Amphibole phases are texturally grouped into inclusion in garnet, the matrix phase,

200   symplectite phase, mantle phase, and vein-filling phase of garnet (Fig. 2 and Table 1).

201   Figure 3 compares chemical compositions among these texturally discerned amphibole

202   groups. The Fe^{3+}/Fe^{2+} value of amphiboles was estimated according to the method

203   proposed by Hawthorne et al. (2012) using ACES_9-8.xlsx provided by Locock (2014).

204   Hawthorne et al. (2012) proposed the $^C(Al + Fe^{3+} + Cr + 2Ti)$–$^A(Na + K)$ diagram as a

205   criterion for classifying the calcium amphibole, where superscript C and A indicate

206   octahedral site and the largest 10 to 12-coordinated site, respectively. However, the

207   parameter $^C(Al + Fe^{3+} + Cr + 2Ti)$ also depends on the amount of the substitution

208    $^BNa^C(Al, Fe^{3+})Ca_{-1}(Mg, Fe^{2+})_{-1}$ in addition to the $^C(Al, Fe^{3+})^TAl(Mg, Fe^{2+})_{-1}Si_{-1}$

209   substitution, where superscripts B and T indicate 8-coordinated site and tetrahedral site,

210   respectively. This point should be considered when discussing the chemical

211   compositions of calcium and sodium-calcium amphibole groups in eclogites and their

212   hydrated lithologies. Therefore, the chemical composition of amphibole will be

213   described by adopting the Si–^BNa diagram in addition to $^C(Al + Fe^{3+} + Cr + 2Ti)$–$^A(Na$

214   + K) diagram.

215

8

Enami and others

216 **Eclogite facies amphibole:** The inclusion and matrix amphibole phases show a relatively

217 wide compositional range from

218 sadanagaite/ferro-sadanagaite–pargasite/ferro-pargasite–taramite/ferro-taramite–

219 katophorite/ferro–katophorite as follows: 5.70–6.51 Si apfu [for 24 (OH, F, Cl, O)],

220 1.32–1.85 ^{C}(Al + Fe^{3+} + Cr + 2Ti) apfu, 0.20–0.66 ^{B}Na apfu, 0.81–0.99 ^{A}(Na + K) apfu,

221 and 0.32–0.61 X_{Mg} [= Mg (Mg + Fe^{2+})] in JDQ03 (Fig. 3a and b); 5.52–6.15 Si apfu,

222 1.06–1.85 ^{C}(Al + Fe^{3+} + Cr + 2Ti) apfu, and 0.41–0.54 X_{Mg} in 91CHXX (Fig. 3c and d).

223 In 91CHXX, the inclusion amphibole has higher ^{B}Na (0.11–0.45 apfu) and lower ^{A}(Na +

224 K) (0.83–0.96 apfu) than the matrix amphibole [0.02–0.08 ^{B}Na apfu and 0.90–1.00 ^{A}(Na

225 +K) apfu], unlike those in JDQ03. Inclusion and matrix amphibole in JDQ03 are rich in

226 Cl and reach 1.8 wt% and 2.4 wt%, respectively, and are poor in F, which is mostly

227 below the detection limit. The Cl and F contents of amphibole in 91CHXX and 91CH08

228 are also mostly below the detection limit, respectively.

229 **Retrograde amphibole:** Retrograde amphibole phases occur as the mantle phase around

230 garnet, crack-filling phase of garnet [Amp (G)], and symplectitic aggregates after

231 omphacite [Amp (S)]. The mantle amphibole around garnet is divided into those that

232 occur between the garnet-symplectitic omphacite boundary [Amp (O)] and garnet-quartz

233 boundary [Amp (Q)]. Amp (Q) is separated from the quartz matrix by a set of thin bands

234 (30–60 μm in width) of plagioclase [Amp (Q) side] and

235 aegirine-diopside/aegirine-hedenbergite (simply denoted as aegirine-diopside hereafter)

236 (quartz side) (Figs. 2d, 6a, and 9). Image processing of reaction zone between the

237 garnet–quartz for four grains using ImageJ (ver. 1.53j) gives volume proportions of

238 about 56–63%, 21–28%, and 10–21% for Amp (Q), aegirine-diopside, and plagioclase,

239 respectively. A thin amphibole-poor and plagioclase-rich band (20–30 μm in width)

9

Enami and others

240   intervenes between the Amp (O) and symplectite after omphacite (e.g., Figs. 4a and 5a).

241   No other phase was observed at the Amp (G)-garnet interface.

242   The mantle amphibole phases around garnet [Amp (O) and Amp (Q)] were divided

243   into the garnet-side (inner) and symplectite/quartz-side (outer) zones based on

244   compositional variations (Figs. 4b, 5b, and 6b, c). The inner and outer zones of the Amp

245   (O) are 20–40 μm and 15–20 μm in width, respectively, and those in the Amp (Q) are

246   relatively wider (60–80 μm in width) and narrower (~10 μm in width) than the Amp

247   (O), respectively. The inner garnet-side zones of the Amp (O) and Amp (Q) are

248   compositionally homogeneous and have atomic Al/Si values [0.63 (2)–0.66 (1)] similar

249   to garnet [0.65 (1)], where the standard deviation in parentheses (1σ level) corresponds

250   to the last digit of the average value. Atomic Ca/Si values are also constant in the inner

251   zones, and are almost identical to those of the garnet in JDQ03 and 91CHXX. In the

252   outer zones of the Amp (O) and Amp (Q) , the Al/Si and Mg/Fe^{2+} values decrease and

253   increase toward the margin, respectively. The Ca/Si value also decreases toward the

254   margin in most outer zones. Consequently, the outermost rim of the Amp (O) has

255   similar chemical composition to the Amp (S) in the symplectite (Figs. 4b, 5b and 6b).

256   The Amp (G) (60–200 μm in width) is compositionally homogeneous (Fig. 6d) and has

257   the Al/Si value [0.64 (2)–0.65 (1)] similar to the garnet and inner garnet-side zones of

258   the Amp (O) and Amp (Q).

259   The Amp (O) in JDQ03 has a wide compositional range and is richer in the edenite

260   component and poorer in the sodic amphibole components than the inclusion phase in

261   garnet and matrix phase: 5.62–6.27 Si apfu, 1.16–1.72 $^{C}(Al + Fe^{3+} + Cr + 2Ti)$ apfu,

262   0.19–0.40 ^{B}Na apfu, 0.84–1.00 $^{A}(Na + K)$ apfu, and 0.45–0.64 X_{Mg} (Fig. 3a and b). The

263   Amp (O) in 91CHXX is poorer in the $^{A}(Na + K)$ component than the matrix phase and in

Enami and others

264   ^{B}Na component than the inclusion phase in garnet: 5.55–6.17 Si apfu, 1.13–1.67 ^{C}(Al +

265   Fe^{3+} + Cr + 2Ti) apfu, 0.04–0.10 ^{B}Na apfu, 0.83–0.96 ^{A}(Na + K) apfu, and 0.47–0.60 X_{Mg}

266   (Fig. 3c and d). The Amp (O), Amp (Q), and Amp (G) in 91CH08 have a similar

267   compositional range, which is relatively limited compared to those in JDQ03 and

268   91CHXX: 5.50–6.03 Si apfu, 1.64–2.00 ^{C}(Al + Fe^{3+} + Cr + 2Ti) apfu, 0.26–0.75 ^{B}Na apfu,

269   0.88–1.00 ^{A}(Na + K) apfu, and 0.27–0.41 X_{Mg} (Fig. 3e and f).

270   The symplectitic Amp (S) is poorer in the tschermak component and higher in X_{Mg}

271   value than the other amphibole phases (Fig. 3): 5.94–6.73 Si apfu, 0.77–1.41 ^{C}(Al + Fe^{3+}

272   + Cr + 2Ti) apfu, 0.12–0.36 ^{B}Na apfu, 0.77–0.98 ^{A}(Na + K) apfu, and 0.60–0.72 X_{Mg} in

273   JDQ03; 6.03–6.29 Si apfu, 1.04–1.23 ^{C}(Al + Fe^{3+} + Cr + 2Ti) apfu, 0.05–0.10 ^{B}Na apfu,

274   0.81–0.96 ^{A}(Na + K) apfu, and 0.53–0.58 X_{Mg} in 91CHXX; and 5.72–6.15 Si apfu,

275   1.62–1.83 ^{C}(Al + Fe_{3+} + Cr + 2Ti) apfu, 0.39–0.82 ^{B}Na apfu, 0.97–1.00 ^{A}(Na + K) apfu,

276   and 0.44–0.66 X_{Mg} in 91CH08.

277   The Cl and F contents of the retrograde amphibole are mostly below the detection

278   limit.

279   **Garnet and other phases**

280   Garnet porphyroblasts are homogeneous, and there is no distinct compositional

281   modification at the interface with the amphibole. They are a grossular-rich

282   almandine-pyrope series and have end-member proportions, which are calculated

283   assuming total iron as FeO, of $Alm_{48–50}Prp_{21–22}Sps_{1–2}Grs_{28–29}$ in JDQ03,

284     $Alm_{47–50}Prp_{17–19}Sps_{1}Grs_{32–34}$ in 91CHXX, and $Alm_{49–53}Prp_{12–14}Sps_{2–3}Grs_{33–36}$ in 91CH08.

285   Small garnet grains included in the Amp (O) and Amp (G) of 91CH08 are distinctly

286   grossular-richer than the garnet porphyroblasts, and their end-member proportions

Enami and others

287   calculated on the basis of charge balance and stoichiometry assuming 8 total cation for 12

288   O (Droop, 1987) are $Alm_{19-32}Prp_{1-3}Sps_{5-8}Grs_{55-68}Adr_{2-8}$.

289   Clinopyroxene grains are grouped into omphacite included in garnet, sodic diopside in

290   the symplectite, and aegirine-diopside in the Amp (Q)–quartz boundary. Omphacite

291   grains are homogeneous and their compositions calculated based on charge balance and

292   stoichiometry (4 total cation for 6 O) are $Jd_{60-64}Di/Hd_{29-33}Aeg_{6-8}$ and 0.60–0.72 X_{Mg} in

293   91CH08. Sodic diopside grains are Jd_{9-28} $Di/Hd_{67-78}Aeg_{5-15}$ and 0.80–0.90 X_{Mg}, Jd_{6-7}

294    $Di/Hd_{72-80}Aeg_{14-22}$ and 0.71–0.81 X_{Mg}, and Jd_{5-24} $Di/Hd_{44-51}Aeg_{25-50}$ and 0.60–0.82 X_{Mg}

295   in JDQ03, 91CHXX, and 91CH08, respectively. Aegirine-diopside grains in 91CH08 are

296   Jd_{2-9} $Di/Hd_{35-54}Aeg_{37-62}$ and 0.21–0.59 X_{Mg}.

297   Anorthite contents of plagioclase grains in the symplectite are An_{8-16}, An_{15-18}, and

298   An_{8-26} in JDQ03, 91CHXX, and 91CH08, respectively. Plagioclase grains around the

299   matrix zoisite in 91CH08 are slightly calcic (~ An_{26}). X_{Fe} [= $Fe^{3+}/(Fe^{3+} + Al)$] values of

300   epidote in JDQ03 are 0.23–0.26. In 91CH08, X_{Fe} values of coexisting prograde zoisite

301   and epidote are 0.04–0.05 and 0.10–016, respectively. Some zoisite and epidote grains

302   have SrO up to 1.2 and 2.7 wt%, respectively (Nagasaki and Enami, 1998).

303

304   **FIB-TEM OBSERVATION**

305   Using the FIB, we cut the selected portion of the interface between the Amp (O) and

306   garnet of 91CHXX. Figure 7 shows the high-angle annular dark-field scanning TEM

307   (HAADF-STEM) and bright field (BF)-TEM images of the investigated TEM foil. The

308   HAADF-STEM (Fig. 7a) and X-ray images show that the Amp (O) and garnet are

309   compositionally homogeneous and their SAED patterns are uniquely consistent with

310   those of calcium amphibole and garnet (Fig. 7a and its insets). The BF-TEM image was

12

Enami and others

311   observed from the [001] direction of the Amp (O), and shows that some subgrain

312   boundaries were developed within the Amp (O) in contrast to the garnet (Fig. 7b). The

313   TEM observations show that the interface between the Amp (O) and garnet form sharp

314   boundaries and no other phases crystallized at the interfaces between these two phases.

315

316   **EBSD ANALYSIS**

317   **Amphibole replacing garnet**

318   The Amp (O), Amp (Q), and Amp (G) show characteristic EBSD images, respectively.

319   The Amp (O) is divided into several segments of 600–700 μm or more in length. Each

320   segment has a nearly identical CPO and is probably a single crystal (Figs. 8a and 9). The

321   Amp (Q) is mainly composed of several segments (200–350 μm in length). Each segment

322   is an aggregate of subgrains (less than 50–100 μm in size) that have similar CPO (Fig. 9).

323   The Amp (G) is composed of an aggregate of anhedral and prismatic crystals (20–80 μm

324   in length), which mostly extend toward the center of the vein from the interface with the

325   host garnet on either side (Fig. 9 and 10a).

326   The Amp (O) and Amp (Q) surround a set of garnet and crack-filling Amp (G) (Figs. 9,

327   10a, and 11a). Figure 10 shows contrasts of CPO patterns and compositional zoning

328   between the Amp (Q) and Amp (G). In the analyzed part, the Amp (Q) is composed of

329   domains 5 and 6 (Fig. 10a). They are composed of several segments, which have a

330   similar crystallographic orientations, respectively (Fig. 10b). However, the domains 7 of

331   the Amp (G) exhibits weak girdles of orientations in (010) and [001], showing different

332   CPOs to the Amp (Q) (Fig. 10b). These data clearly suggest that the Amp (G) is cut by the

333   Amp (Q). A similar relationship was also observed between the Amp (G) and Amp (O)

334   (right part of Fig. 9 and left-lower part of Fig. 11a). As shown in a compositional zoning

Enami and others

335 through the boundary between the Amp (G) and Amp (Q) (Fig. 10c), part of the Amp (G)

336 was compositionally homogeneous and its Al/Si value [0.65 (1)] is similar to that of the

337 porphyroblastic garnet [0.65 (0)]. In contrast, in the Amp (Q) part, the Al/Si and Ca/Si

338 values decrease and Mg/Fe^{2+} value increases toward the outermost margin and reach 0.51,

339 0.18, and 0.51, respectively.

340

341 **CPO relationship between Amp (O) and Amp (S)**

342 The EBSD mappings of boundaries between the Amp (O) and Amp (S) domains,

343 which are in contact with each other, qualitatively show that these two-types of

344 amphibole share similar CPO patterns (Figs. 8a, 9 and 11a). Figure 11b and c

345 quantitatively compare the CPO patterns of the Amp (O) and Amp (S), which constitute

346 bordering domains. Each set of neighboring Amp (O) and Amp (S) shows a similar CPO

347 pattern; thus, the two Amp (O) domains, which are located on either side of the Amp (S)

348 domain, also share a similar CPO pattern: e.g., sets of domains 8, 9, and 10 (Fig. 11b) and

349 domains 11, 12, and 13 (Fig. 11c). The Amp (O) segment and Amp (S) grains are

350 sometimes continuous at their interface, thus forming a single crystal (cf. the parts

351 enclosed by the circles in Figs. 8a and 11a).

352

353 **CPO relationship between Amp (S) and symplectitic sodic diopside**

354 The CPO data show that the symplectitic sodic diopside grains form a domain structure

355 with the same crystal orientation (Fig. 8b). The ranges of the sodic diopside domain are

356 almost identical to those of the Amp (S) domain, and these two phases share the same

357 orientations of (100), (010), and [001] for each domain (Fig. 8c and d).

358

14

Enami and others

359   **FORMATION CONDITIONS OF AMPHIBOLE**

360   Symplectite amphibole [Amp (S)] and mantle amphibole around the garnet [Amp (O)

361   and Amp (Q)] closely coexist with plagioclase, suggesting that the assemblage of these

362   two phases formed during the exhumation and hydration stage of the eclogites. The

363   Amp (O) and Amp (Q) are systematically zoned and have minimum Al/Si and Ca/Si

364   values and maximum Mg/Fe^{2+} value at the interface with plagioclase (Figs. 4b, 5b, and

365   6b, c). Their interface chemical compositions might have represented the final

366   recrystallization of these two phases.

367   The following net-transfer reactions were proposed for a calcic

368   amphibole-plagioclase geothermometer (Blundy and Holland, 1990; Holland and

369   Blundy, 1994):

370    $NaCa_2(Mg, Fe^{2+})_5(AlSi_7)O_{22}(OH)_2 + 4\ SiO_2$

371        $= Ca_2(Mg, Fe^{2+})_5Si_8O_{22}(OH)_2 + NaAlSi_3O_8$ (R1)

372    $NaCa_2(Mg, Fe^{2+})_4Al(Al_2Si_6)O_{22}(OH)_2 + 4\ SiO_2$

373        $= Ca_2(Mg, Fe^{2+})_4Al(AlSi_7)O_{22}(OH)_2 + NaAlSi_3O_8$ (R2)

374    $NaCa_2(Mg, Fe^{2+})_5(AlSi_7)O_{22}(OH)_2 + NaAlSi_3O_8$

375        $= Na(NaCa)(Mg, Fe^{2+})_5Si_8O_{22}(OH)_2 + CaAl_2Si_2O_8$ (R3)

376   However, the amphiboles discussed in this paper are significantly rich in the $^A(Na + K)$

377   component, which is usually >0.8–0.9 apfu (Fig. 3), and probably contain little amount

378   of the edenite-free end-member components such as tremolite and hornblende.

379   Therefore, the tremolite- or hornblende-bearing geothermometers [reactions R1and R2]

380   would be inappropriate for estimating the temperature of the aluminous

381   amphibole-bearing equilibrium. Consequently, a combination of the reaction R3 for the

382   geothermometer [thermometer B of Holland and Blundy (1994)] and the Al/Si

15

Enami and others

383   partitioning between amphibole and plagioclase for the geobarometer (Molina et al.,

384   2015) was employed for the P-T estimations (Table 2). Compositions of the outermost

385   parts of the Amp (O) and Amp (Q), which contact plagioclase (cf. Figs. 4a–6a), were

386   used for the P/T calculations. On the other hand, average compositions were employed

387   for plagioclase and Amp (S). The pairs of Amp (O)/Amp (Q)/Amp (S) and plagioclase

388   showed similar equilibrium conditions with each other and those of samples are as

389   follows: 0.87 (6)–0.97 (4) GPa/674 (16)–675 (4) °C for JDQ03; 0.83 (2)–0.92 (2)

390   GPa/686 (10)–701 (6) °C for 91CHXX; and 1.28 (18)–1.33 (20) GPa/694 (14)–729

391   (22) °C for 91CH08, where the number in parentheses indicates the standard deviation

392   (1σ level) (Table 2).

393   　The Donghai eclogites are considered to have experienced nearly isothermal

394   decompression at the beginning of exhumation, and their P/T conditions at peak

395   metamorphic and/or early exhumation stages were estimated at around 3.2–3.6

396   GPa/680–840 °C (Zhang et al., 1995, 2005; Frezzotti et al., 2007; Li et al., 2011; Curetti

397   et al., 2018; Li et al., 2018). The estimated formation temperatures of the aluminous

398   amphibole-plagioclase pairs are within the range of those reported during UHP

399   metamorphism, and are consistent with the exhumation P-T path of nearly isothermal

400   decompression discussed by many authors (Fig. 12).

401

402   **DISCUSSION**

403   **Stability of aluminous amphibole**

404   　Sadanagaite and related aluminous calcium amphibole generally occur in

405   SiO_2-undesaturated lithologies as summarized in Mogessie et al. (1986), Hawthorne and

406   Harlow (2008), and the current study. These limited modes of occurrences might indicate

16

Enami and others

407   that the Si-undersaturated system strongly promotes the formation of aluminous

408   amphibole. However, aluminous amphibole phases occasionally occur in retrograde

409   coesite and/or quartz-bearing eclogites as described in this study and reported in

410   additional work, for example, Mogessie et al. (1986). Total Al, ^{C}Al, and Al/Si values of

411   calcium amphibole coexisting with plagioclase systematically increase with increasing

412   pressure, at least up to 1.2–1.5 GPa (Molina et al., 2015); thus, relatively high-pressure

413   conditions might contribute to the stabilization of the aluminous calcium amphibole in

414   plagioclase-bearing assemblage.

415   Stable amphibole phases of the eclogite facies stage are generally sodium–calcium

416   amphibole of the barroisite–taramite/katophorite series (e.g., Massonne, 2012; Yamasaki

417   et al., 2018). In contrast, aluminous amphibole phases were generally reported as

418   retrograde products (e.g., Palin et al., 2014; Chatterjee and Jagoutz, 2015; O'Brien, 2019),

419   although those with ~5.8 Si apfu and ~3.3 Al apfu were also reported as inclusions in the

420   garnet of eclogites from the Western Gneiss Region (e.g., Medaris et al., 2018). These

421   data likely suggest that relatively high-pressure environments might be a necessary

422   condition, but are not sufficient for the formation of aluminous amphibole in eclogites

423   and their retrograde lithologies.

424   The aluminous amphibole in the Donghai eclogites exhibits several different textures

425   and compositional zonings, which are key to understanding the origin of aluminous

426   amphibole in the coesite/quartz-bearing eclogites. The mantle amphibole around garnet

427   [Amp (O) and Amp (Q)] and crack-filling amphibole [Amp (G)] exhibit different

428   interface textures that are closely related to the phase they contacted. A set of thin bands

429   of plagioclase and aegirine-diopside develops between the Amp (Q) and quartz (Fig. 6a).

430   However, no other phase was observed at the boundaries between the Amp (O) and

17

Enami and others

431   symplectite and between the Amp (G) and garnet (Figs. 4a–6a). The Amp (O) and Amp

432   (Q) consist of the inner garnet-side and outer matrix-side zones, which are

433   compositionally homogeneous and monotonically zoned, respectively (Figs. 4b, 5b, and

434   6b, c). The Amp (G), on the other hand, is homogeneous and has a chemical

435   composition similar to that of the inner zone of the Amp (O) and Amp (Q). The

436   coexistence of these three types of amphibole was observed to have occurred at the

437   varying parts of a garnet grain (Figs. 6a and 9). These textural and compositional

438   differences suggest that the recrystallizations of aluminous amphibole replacing garnet

439   was controlled by individual reactions that proceeded locally in each domain.

440

441   **Formation process of amphibole in the Donghai eclogite**

442   Figure 13 shows a possible formation model of the aluminous amphibole in the

443   Donghai eclogites. Although a minor calcium amphibole occurs as inclusions in garnet,

444   and the matrix phase in the eclogite facies and early exhumation stages, the initial major

445   mafic phases were garnet and omphacite (Fig. 13a), which have eventually been

446   replaced by calcium amphibole through subsequent hydration reactions.

447

448   **Formations of crack-filling and mantle amphiboles:** The compositional similarity of

449   the inner zones of the Amp (O) and Amp (Q) to the Amp (G) indicates that these zones

450   are considered to have formed as pseudomorphs after garnet, similarly to the Amp (G).

451   However, the following characteristics could be observed between the Amp (O)/Amp

452   (Q) and Amp (G): (1) The CPO pattern is discontinuous at the boundaries between them

453   (Figs. 10b and 11b, c), and (2) the Amp (G) is texturally cut or partly surrounded by the

454   Amp (O) or Amp (Q) (Figs. 9, 10a, and 11a). These textural characteristics likely

18

Enami and others

455   suggest that the Amp (G) first replaced garnet along cracks (Fig. 13b), and then the

456   Amp (O)/Amp (Q) formed slightly later. The Amp (G) was probably formed in

457   connection with the hydraulic fracturing process in the early stages of hydration, while

458   the Amp (O) and Amp (Q) were subsequently formed by hydration reactions caused by

459   subsequent grain-boundary processes.

460   Two models of 1 and 2 are assumed for the formation process of the Amp (O) and

461   Amp (Q). Model 1 interprets that: (1) the end of the Amp (G) stretch direction [point X:

462   boundary between the Amp (G) and Amp (Q) of Fig. 10a, c] was an initial surface of a

463   garnet porphyroblast before formation of the Amp (O) and Amp (Q), and (2) the Amp

464   (O) and Amp (Q) have been initially nucleated at the interface between garnet and

465   omphacite/quartz, and then grew to replace the garnet (inward) and symplectite/quartz

466   (outward), respectively (Fig. 13d1). This model suggests that (1) the boundary between

467   the inner and outer zones of Amp (O) and Amp (Q) is almost identical to the initial

468   surface of the garnet porphyroblast (white broken line in Fig. 13d1) and thus, the inner

469   zone is a pseudomorph after garnet and the outer zone occupies the original matrix part.

470   In contrast, model 2, assumes that the Amp (O) and Amp (Q) are pseudomorphs after

471   garnet in their entirety (Fig. 13c), and that their outer zones represent parts whose

472   chemical composition has been modified by later re-equilibration (Fig. 13d2). In this

473   model, the textural relationships between the Amp (G) and Amp (O)/Amp (Q) shown in

474   Figs. 9, 10a, and 11a are explained as a partial resetting of the chemical composition

475   and COP of Amp(G) during the formation of the outer zone. However, this

476   interpretation does not well explain why the chemical composition and CPO of the Amp

477   (G) were not modified at the stage when the Amp (O)/Amp (Q) were initially formed

478   (Fig. 13c). In addition to this issue, the singular value decomposition (SVD) analysis of

19

Enami and others

479 the reaction zone at the Amp (Q)–Qz boundary indicates that the volume of Amp (Q)

480 formed by the assumed hydration reaction was likely to have been larger than that of the

481 consumed garnet, as described later. Therefore, the model 1 seems to better explain the

482 formation process of the inner and outer zones of mantle amphibole.

483

484 **Formations of Amp (S) and Amp (O):** The amphibole phases in symplectite [Amp

485 (S)] form domains of 300–700 μm in size, in which they share similar crystallographic

486 orientation (Figs. 8a, c and 11). These domains contain sodic diopside particles with

487 similar crystallographic orientation in each domain (Fig. 8b, d). Furthermore, the Amp

488 (S) and sodic diopside characteristically show almost the same CPO pattern in each

489 domain (Fig. 8c, d). The sodic diopside + plagioclase symplectite was considered to

490 have formed by the replacement of omphacite at early exhumation stage, and the Amp

491 (S) was subsequently grown under the strong control by the crystal orientation of the

492 symplectitic sodic diopside with progressive infiltration of metamorphic fluid (Fig.

493 13c).

494   A set of the Amp (O) and Amp (S) in contact shares a similar CPO pattern, and thus,

495 several Amp (O) segments occurring around a symplectite domain all share a common

496 CPO (e.g., set of domains 8 and 9 and set of domains 11 and 12 in Fig. 11). These CPO

497 data indicate that the Amp (S) in symplectite domain served to have linked the

498 crystallographic orientations of the several Amp (O) domains around the symplectite.

499 The recrystallizations of the Amp (O) and Amp (S) likely began almost simultaneously,

500 and the Amp (O) grew in synchronization with the crystallographic orientation of the

501 Amp (S) (Fig. 13c or d1). The Amp (Q) may also have formed at a similar stage as the

502 Amp (O) and Amp (S).

Enami and others

503   The textural and CPO relationships suggest that the (1) sodic diopside + plagioclase

504   symplectite had probably formed before the Amp (S), (2) the Amp (G) formed slightly

505   earlier than the Amp (O) and Amp (Q), and (3) the Amp (O) and Amp (Q) formed at

506   about the same stage as Amp (S). However, it is unclear whether the formation of

507   symplectitic sodic diopside preceded that of the Amp (G), or if these phenomena were

508   nearly simultaneous (Fig 13b). The Amp (G) was probably formed in connection with

509   hydraulic micro-fracturing process in the early stages of hydration, while Amp (O),

510   Amp (Q), and possibly Amp (S) were subsequently formed by hydration reactions

511   caused by grain-boundary processes (e.g., Putnis and Austrheim, 2010).

512

513   **Formation of aluminous calcium amphibole in SiO$_2$-saturated rocks**

514   The inner zones of the Amp (O) and Amp (Q), which are pseudomorphs after garnet,

515   are compositionally homogeneous and their Al/Si values are significantly similar to

516   those of garnet (Fig. 4b, 5b, and 6b, c). The Al/Si value of the Amp (G) is also similar

517   to that of garnet (Fig. 6d). Additionally, the FIB-TEM and EMPA observations of the

518   amphibole-garnet interface in micro- and nano-scales demonstrated that Amp (O), Amp

519   (Q), and Amp (G) are single phase and contain no other phases. These data may indicate

520   that the inner zone of the Amp (O), Amp (Q), and Amp (G) would grow by simple

521   substitution of garnet, using tetrahedral and octahedral cations (Si and Al) of the garnet

522   as the basic framework.

523   Diffusion coefficients of major elements in amphibole are not well understood.

524   However, in the case of pyroxene, which has similar crystal structure of inosilicates to

525   amphibole, diffusion coefficients of Ca, Al, and Si are one to three orders of magnitude

526   lower than those of Mg and Fe^{2+} (Cherniak and Dimanov, 2010). Considering these

21

Enami and others

527 diffusion coefficients of pyroxene as a reference, the inner zones of the Amp (O) and

528 Amp (Q) might have been formed by the preferential diffusion of Mg, Fe^{2+}, and alkali

529 elements between garnet and the matrix. Whereas, Si and Al, which have smaller

530 diffusion coefficients, likely did not migrate much, and contributed to the growth of

531 amphibole with little change in their ratio from the garnet value. This process, coupled

532 with hydration and a significantly local reaction, may have allowed the formation of

533 aluminous calcium amphibole in the quartz-bearing eclogites from the Donghai area,

534 Sulu UHP metamorphic belt.

535 In JDQ03 and 91CHXX, the Ca/Si values of the aluminous amphibole are also

536 similar to those of garnet (Figs. 4b and 5b). Calcium, in addition to Si and Al, did not

537 diffuse much during the inner zone growth in these samples. The Ca/Si value of the

538 aluminous amphibole in 91CH08 are lower than those of garnet (Fig. 6a, b, c), unlike

539 JDQ03 and 91CHXX. The garnet grains in 91CH08 are richer in the Grs component

540 [34.9 (1.0) mol.%] than those in JDQ03 [27.5 (1.8) mol%] and 91CHXX [33.0 (0.5)

541 mol%]. Therefore, small Grs-rich garnet grains were nucleated during the hydration stage

542 of garnet, which would have decreased the Ca/Si value of the aluminous amphibole.
543

544 **Numerical examination of mantle amphibole formation:** Textural characteristics

545 suggest that the Amp (Q) with aegirine-diopside and plagioclase at the boundary between

546 garnet and quartz were formed by infiltration of metamorphic fluid dissolving sodium,

547 potassium, and some other elements in the following qualitative reaction:

548 $\qquad$ Grt + Qz + Na_2O + O_2 + H_2O = Amp (Q) + Aeg-di + Pl $\qquad$ (R4)
549 The possibility of deriving the reaction R4 was investigated using the SVD method

550 (Fisher, 1989; Nishiyama et al., 2017) based on the assumption of conservation of SiO_2,

22

Enami and others

551   Al_2O_3, and CaO and considering discussions in the previous section. Other components

552   such as FeO, MgO, MnO, $NaO_{1/2}$, $KO_{1/2}$, and H_2O are treated as mobile components. The

553   cation proportions and molar volumes of the minerals in 91CH08 employed for the SVD

554   calculation are listed in Table 3. The volume of the outer zone of Amp (Q) is distinctly

555   smaller than that of the inner zone (cf. Fig. 6c), and thus, the average composition of the

556   inner zone was adopted as the composition of the product Amp (Q) for the calculation.

557   The sample does not contain any Fe-oxide phase, and garnet and quartz assumed as

558   reactants do not contain Fe_2O_3 as a major component. Therefore, in the calculations,

559   Fe_2O_3 contents in the products of Amp (Q) and aegirine-diopside were assumed to not

560   have been supplied from outside the system, instead, primarily by oxidation of FeO in

561   the reactant garnet during the reaction progress.

562   We constructed a matrix of mineral compositions given in the atomic proportions per

563   formula unit in the system SiO_2-Al_2O_3-CaO as shown by superscript a in Table 3. The

564   SVD of the matrix gives the following two reactions:

565   -0.704 Grt $- 0.477$ Qz $+ 0.416$ Amp $+ 0.299$ Aeg-di $- 0.119$ Pl $= 0$ (R5)

566   and

567   -0.342 Grt $+ 0.771$ Qz $+ 0.314$ Amp $- 0.173$ Aeg-di $- 0.401$ Pl $= 0$.   (R6)

568   Both the R5 and R6 do not represent the proper reaction relation that explains the texture

569   of Amp (Q) and related phases. However, the linear combination of these two reactions,

570   (R5) $- a$(R6), can represent the proper reaction relation in some range of the value of

571   parameter $a = \xi_6/\xi_5$, where ξ_5 and ξ_6 represent the reaction extents of R5 and R6,

572   respectively. We get

573     $(-0.704 + 0.342a)$ Grt $+ (-0.477 - 0.771a)$ Qz $+ (0.416 - 0.314a)$ Amp

574          $+ (0.299 + 0.173a)$ Aeg-di $+ (-0.119 + 0.401a)$ Pl $= 0$ (R7)

Enami and others

575   The stoichiometric coefficients of minerals give proper signs, positive for products (Amp,

576   Aeg-di, and Pl) and negative for reactants (Grt and Qz), when $0.30 < a < 1.33$.

577   Figure 14 shows the volume changes of minerals based on the calculated

578   stoichiometric coefficients of minerals as functions of the parameter a and their molar

579   volumes listed in Table 3. Although the volume of the product amphibole and the reactant

580   garnet both decrease as the parameter a increases, the decreasing ratio is greater for the

581   amphibole (Fig. 14a). Thus, when the parameter a is less than 0.68, the volume of the

582   product amphibole exceeds that of the consumed garnet, and this relationship is reversed

583   at $a > 0.68$. Figure 14b shows the relationship between parameter a and the volume

584   proportions of Amp(Q), aegirine-di, and plagioclase in the reaction zone calculated by

585   SVD method. This figure also indicates the range of parameter a that can simulate the

586   volume proportions of these minerals for the four grains in 91CH08 estimated by image

587   processing. As the parameter a increases, the Amp (Q) volume proportion in the reaction

588   zone systematically decreases, and those of arginine-diopside and plagioclase increase.

589   Thus, the abundance ratios of amphibole, aegirine-diopside, and plagioclase become

590   similar to each other as the parameter a increases, and they become almost equal when the

591   parameter a is about 1.0. The estimated volume range of Amp (Q) for four grains

592   (56–63% and 61% in average) gives a relatively narrow range of parameter a

593   (0.58–0.69). On the other hand, the ranges of parameter a assumed from the volumes of

594   aegirine-diopside (21–28% and 25 % in average) and plagioclase (10–21% and 15 % in

595   average) are 0.34-0.70 and 0.55-0.79, respectively, which are wider than those

596   estimated by Amp (Q). This is due to that the rate of change of volume of

597   aegirine-diopside and plagioclase for parameter a is significantly smaller than that of

598   Amp (Q). Therefore, it would be appropriate to discuss the range of parameter a from

24

Enami and others

599   the volume estimate of Amp (Q), rather than referring to that of aegirine-diopside and

600   plagioclase (Fig. 14b). The reaction zone seems to be best simulated by assuming that

601   the parameter a is around 0.6. The range of parameter a estimated from the average

602   volumes of Amp (Q), aegirine-diopside, and plagioclase is 0.53-0.65, which is almost

603   identical to the value estimated from Amp (Q). These data suggest that the reaction zone

604   probably formed under conditions where the volume of product Amp (Q) was larger

605   than that of consumed garnet. Consequently, the SVD analysis also indicates that the

606   model 1 shown in Fig. 13 is appropriate to explain the formation process of aluminous

607   amphibole.

608   Stoichiometric coefficients of mobile components are also calculated by combining the

609   stoichiometric coefficients of minerals and the mineral compositions (Fig. 14c). The

610   conspicuous feature is that all mobile components are added from the exterior to form the

611   Amp (Q) – (Aeg-di) - Pl reaction zone. The results by SVD analysis suggest that under

612   certain conditions with infiltration of the metamorphic fluid, the R4 reaction can

613   proceed to form the mineral combination observed in 91CH08.

614

615   **IMPLICATIONS**

616   The formation process of retrograde amphiboles replacing garnet in the Donghai

617   eclogites strongly depends on the mineral phases in contact with the garnet, and is an

618   extremely local phenomenon. The range of chemical equilibrium was narrow and

619   probably less than several tens of micrometers in size. Hacker et al. (2009) compiled

620   chronological data of their new analyses and those published in literature, and pointed out

621   the rapid exhumation of Sulu UHP terrane to a crustal level (0.5–2.5 cm/yr) and a

622   relatively short duration of subsequent amphibolite facies metamorphism with rapid

25

Enami and others

623   cooling (50–200 °C/Myr). Liu and Liou (2011) estimated the exhumation rate of the

624   Dabie-Sulu UHP metamorphic belt as 0.5 –1.13 cm/yr based on the U-Pb SHRIMP ages

625   of zircon grains. Taguchi et al. (2018) reported the amorphous SiO_2 phase containing

626   nanocrystalline quartz in pseudomorphs after coesite from the Yangzhuang area near the

627   Donghai area, and suggested a rapid cooling during amphibolite facies and subsequent

628   stages. These rapid cooling processes might have maintained a very local and limited

629   element transfer and advanced the crystallization of aluminous amphiboles in the

630   Donghai eclogites.

631   The rapid exhumation and cooling of HP-UHP eclogites were also reported from

632   other continent-continent collision zones, such as the Alps metamorphic region (1.6–3.4

633   and >3.6 cm/yr and 85–100 °C/Myr: e.g.,Gebauer et al., 1997; Rubatto and Hermann,

634   2001; Glodny et al., 2005) and Kokchetav Massif, Kazakhstan (several

635   millimeters–several centimeters/yr: e.g., Katayama et al., 2001; Hacker et al., 2003;

636   Dobretsov and Shatsky, 2004). Aluminous amphibole pseudomorphs after garnet, which

637   show texture similar to the case of the Donghai eclogite, were reported from retrograde

638   eclogites in Central Oetztal, the eastern Alps (Mogessie et al., 1986) and Tso Morari

639   Massif, Himalaya (e.g., Palin et al., 2014; Chatterjee and Jagoutz, 2015). The aluminous

640   calcium amphiboles might have widely formed during rapid exhumation as a retrograde

641   product even in SiO_2-saturated eclogites, especially as a pseudomorph after garnet.

857   Figure 1. (a) Simplified map of the Sulu region showing major tectonic units and the

858   position of the Donghai area (slightly modified Fig. 1 from Zhang et al., 2008). (b)

859   Schematic geological map showing the distribution of eclogites in the Donghai

860   area and sample localities (slightly modified Fig. 2 from Zhang et al., 1995).

861   Abbreviations: WQY fault, Wulian–Qingdao-Yantai fault; JX fault,

862   Jiashan-Xiangshui fault.

863   Figure 2. (a), (b), and (d) Polarizing microscope photographs (plane polarized light) and

864   (c) back-scattered electron (BSE) image of quartz-bearing eclogites from the

865   Donghai area, Sulu UHP metamorphic belt. CaKα X-ray and electron

866   back-scattered diffraction (EBSD) pattern maps of the area of (d) are shown in

867   Fig. 6a and 9, respectively. Abbreviations: Symp, symplectite after omphacite.

868   Figure 3. Compositional ranges of amphibole in eclogites of (a) JDQ03, (b) 91CHXX,

869   and (c) 91CH08 from the Donghai area, Sulu UHP metamorphic belt, on the ^{C}(Al

870   + Fe^{3+} + Cr + 2Ti)–^{A}(Na +K) and Si–^{B}Na diagrams. * Some ferro-sadanagaite

871   and ferro-taramite grains belong to potassic category with K > Na in the A site.

872   Figure 4. (a) Back-scattered electron (BSE) image showing textural relationship of garnet

873   porphyroblast, Amp (O), and Amp (S) in an eclogite (JDQ03) from the Donghai

874   area, Sulu UHP metamorphic belt. (b) Step-scan analysis of the amphibole around

875   garnet along the line A-A' in Fig. 4a, and comparison of its compositional range

876   with those in symplectite and the matrix. Abbreviations are: av, average; max,

877   maximum; med, median: min, minimum. * Outliers are not plotted.

878   Figure 5. (a) Back-scattered electron (BSE) image showing textural relationship of garnet

879   porphyroblast, Amp (O), and Amp (S) in an eclogite (91CHXX) from the

37

Enami and others

880   Donghai area, Sulu UHP metamorphic belt. (b) Step-scan analysis of the

881   amphibole around garnet along the line B-B' in Fig. 5a, and comparison of its

882   compositional range with those in symplectite and the matrix. * Outliers are not

883   plotted.

884   Figure 6. (a) CaKα X-ray map showing textural relationship of garnet porphyroblast and

885   amphibole [Amp (O), Amp (Q), Amp (G), and Amp (S)] in an eclogite (91CH08)

886   from the Donghai area, Sulu UHP metamorphic belt. Step-scan analyses of the

887   amphibole segments between (b) garnet and symplectite and between (c) garnet

888   and quartz along the lines C-C' and D–D' in Fig. 6a, respectively. Figure 6b

889   compares the compositional range of the Amp (O) segment with those in

890   symplectite [Amp (S)]. (d) Step-scan analysis of crack-filling amphibole

891   segments [Amp (G)] between garnet segments along the line E-E' in Fig. 6a. *

892   Outliers are not plotted.

893   Figure 7. (a) High-angle annular dark field scanning TEM (HAADF-STEM) image and

894   (b) bright-field (BF)-TEM image of subsilicic amphibole–garnet interface in an

895   eclogite (91CHXX) from the Donghai area, Sulu UHP metamorphic belt.

896   Bright-field TEM image of the interface structures was viewed along the [001]

897   zone axis of aluminous amphibole.

898   Figure 8. Electron back-scattered diffraction (EBSD) pattern maps of (a) Amp (O) and

899   Amp (S) and (b) symplectitic sodic diopside in an eclogite (91CHXX: 1 μm grid

900   step). Pole figures for crystallographic orientations of (100), (010), and [001] of

901   the (c) Amp (S) and (d) sodic diopside particles in the selective domains 1–4 of

902   symplectite. Data N indicates the number of analysis particles. Circles in (a)

903   indicate direct connection between Amp (O) and Amp (S).

Enami and others

904   Figure 9. Electron back-scattered diffraction (EBSD) pattern map of Amp (O), Amp (Q),

905   Amp (G), and Amp (S) in an eclogite (91CH08: 2 μm grid step) from the Donghai

906   area, Sulu UHP metamorphic belt.

907   Figure 10. (a) Electron back-scattered diffraction (EBSD) pattern map (1 μm grid step) of

908   Amp (Q) and Amp (G) in an eclogite (91CH08) from the Donghai area, Sulu UHP

909   metamorphic belt. (b) Equal-area and lower hemisphere projection showing

910   crystallographic orientations of the Amp (Q) and Amp (G) segments. Data n

911   indicates the number of analysis points. (c) Step-scan analysis of the boundary

912   between the Amp (Q) and Amp (G) segments along the line F-F' in Fig. 10a.

913   Figure 11. (a) Electron back-scattered diffraction (EBSD) pattern map (1 μm grid step) of

914   Amp (O), Amp (G), and Amp (S) in an eclogite (91CH08) from the Donghai area,

915   Sulu UHP metamorphic belt. Equal-area and lower hemisphere projection

916   comparison of crystallographic orientations of the Amp (O) and Amp (S)

917   segments in the sets of (b) domains 8, 9, and 10 and (c) domains 11, 12, and 13.

918   Data n indicates the number of analysis points. Circles in (a) indicate a direct

919   connection between Amp (O) and Amp (S).

920   Figure 12. Comparison of the estimated equilibrium P-T conditions of aluminous

921   calcium amphiboles + plagioclase (this study) and the exhumation P-T path of

922   Donghai eclogites reported in literature. Abbreviations for references are: C18,

923   Curetti et al. (2018); F07, Frezzotti et al. (2007); L11, Li et al. (2011); L18, Li et

924   al. (2018); Z95, Zhang et al. (1995); Z05, Zhang et al. (2005). Geothermometer

925   (HB94) and geobarometer (M15) are from Holland and Blundy (1994) and

926   Molina et al. (2015), respectively. The univariant lines of Dia-Gr, Coe-Qz,

927   Ab-Jd+Qz, and Al_2SiO_5 phases were calculated using THERMOCALC software

Enami and others

928   ver. 3.33 (Powell and Holland, 1988), internally consistent thermodynamic data

929   set (Holland and Powell, 1998; updated June 2009), and program AX_2

930   (https://filedn.com/lU1GlyFhv3UuXg5E9dbnWFF/TJBHpages/ax.html).

931   Figure 13. Conceptual diagram of growth scenarios (Models 1 and 2) of retrograde

932   amphiboles in the Donghai eclogites, Sulu UHP metamorphic belt during the

933   exhumation and hydration stage. (a) Eclogite facies and early exhumation stage.

934   (b) Formations of sodic diopside + plagioclase symplectite and crack-filling

935   amphibole [Amp (G)] at the early exhumation and hydration stage, although it is

936   not clear which of these phenomena proceeded first, or if they were nearly

937   simultaneous. (c) Formations of mantle amphibole around garnet [Amp (O) and

938   Amp (Q)] and symplectitic amphibole [Amp (S)] (Model 2). (d1) Initial

939   nucleation of amphibole at the interface between garnet and symplectite of sodic

940   diopside + plagioclase, and subsequent growth of Amp (S) and Amp (O)/Amp

941   (Q). The inner and outer zones of Amp (O) and Amp (Q) grew inward and

942   outward from the initial surface of the garnet (dashed line), respectively (Model

943   1). (d2) The formation of the inner and outer zones of Amp (O) and Amp (Q) by

944   modification of the chemical composition of their outer parts due to

945   re-equilibration (Model 2).

946   Figure 14. Volume change of minerals [(a) in cm^3 and (b) %] based on the calculated

947   stoichiometric coefficients of minerals as a function of $a = \xi_6/\xi_5$, where ξ_5 and ξ_6

948   represent the reaction extents of R5 and R6 in the text, respectively. The mineral

949   volumes were estimated using the molar volumes listed in Table 3. The

950   estimated volume proportions (%) of Amp (Q), aegirine-diopside, and

951   plagioclase in the reaction zone are plotted in Fig. 14b for discussion on the

40

Enami and others

952   possible range of the parameter a. (c) Stoichiometric coefficients of mobile

953   components as a function of the parameter a.

(a) High-angle annular dark field scanning TEM (HAADF-STEM) image and (b) bright-field (BF)-TEM image of aluminous amphibole–garnet interface in an eclogite (91CHXX) from the Donghai area, Sulu UHP metamorphic belt. Bright-field TEM image of the interface structures was viewed along the [001] zone axis of aluminous amphibole.

Fig. 7 (Enami and others)
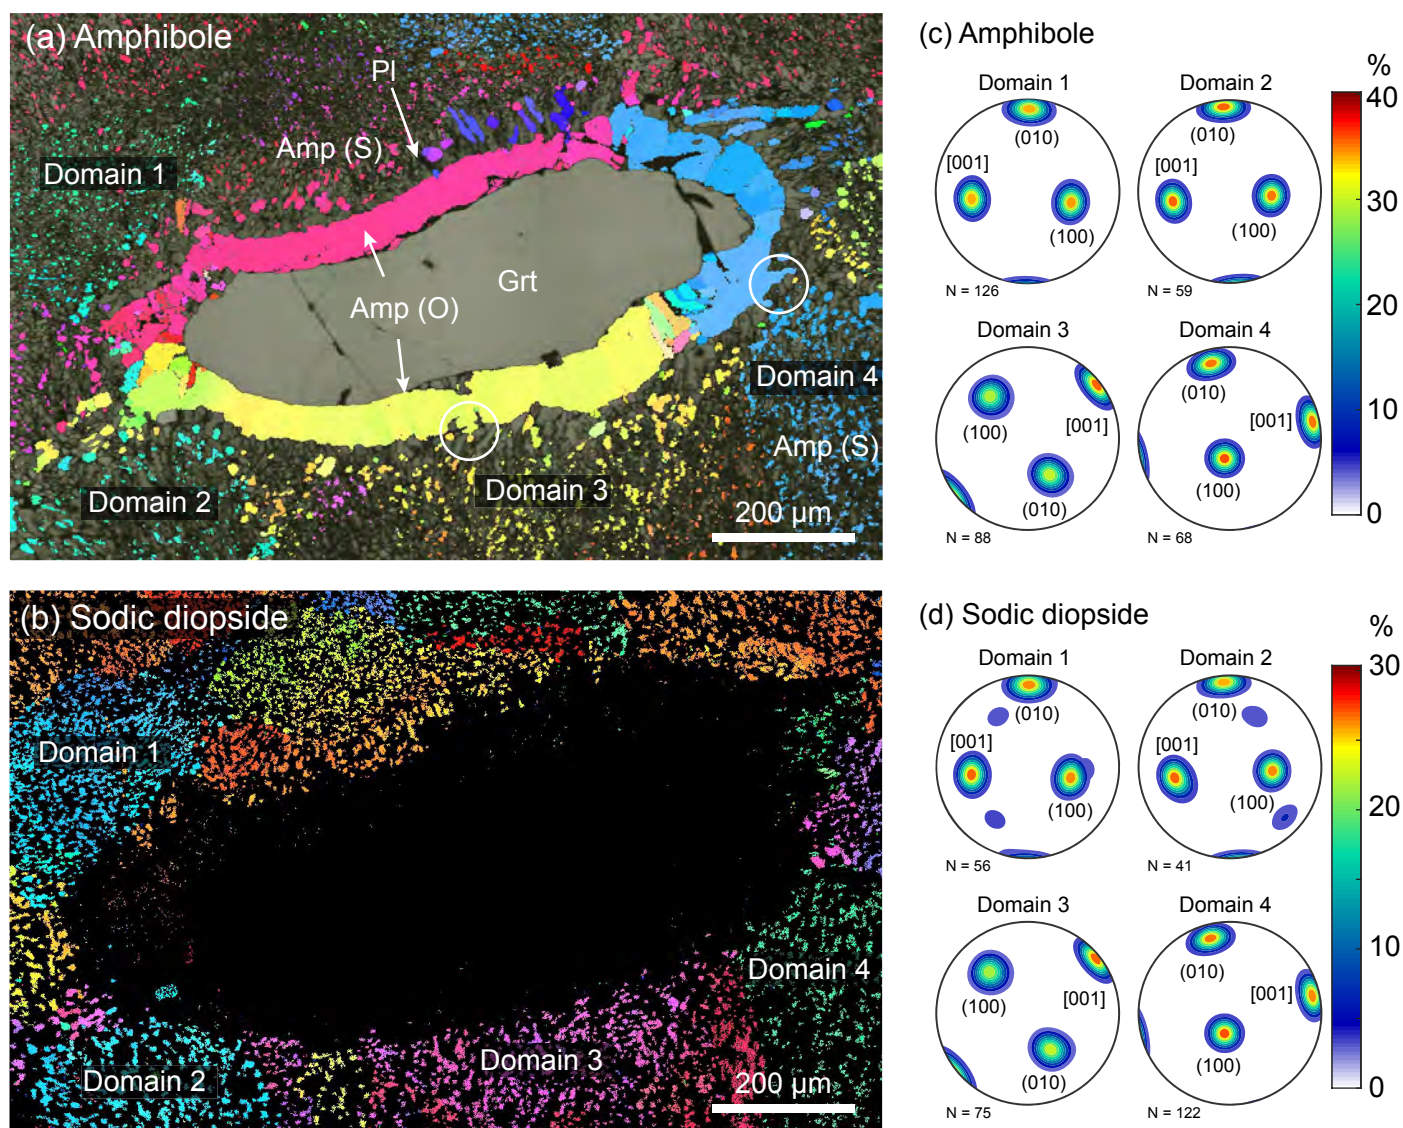

Figure 8. Electron back-scattered diffraction (EBSD) pattern maps of (a) Amp (O) and Amp (S) and (b) symplectitic sodic diopside in an eclogite (91CHXX: 1 µm grid step). Pole figures for crystallographic orientations of (100), (010), and [001] of the (c) Amp (S) and (d) sodic diopside particles in the selective domains 1–4 of symplectite. Data N indicates the number of analysis particles. Circles in (a) indicate a direct connection between Amp (O) and Amp (S).

Fig. 8 (Enami and others)
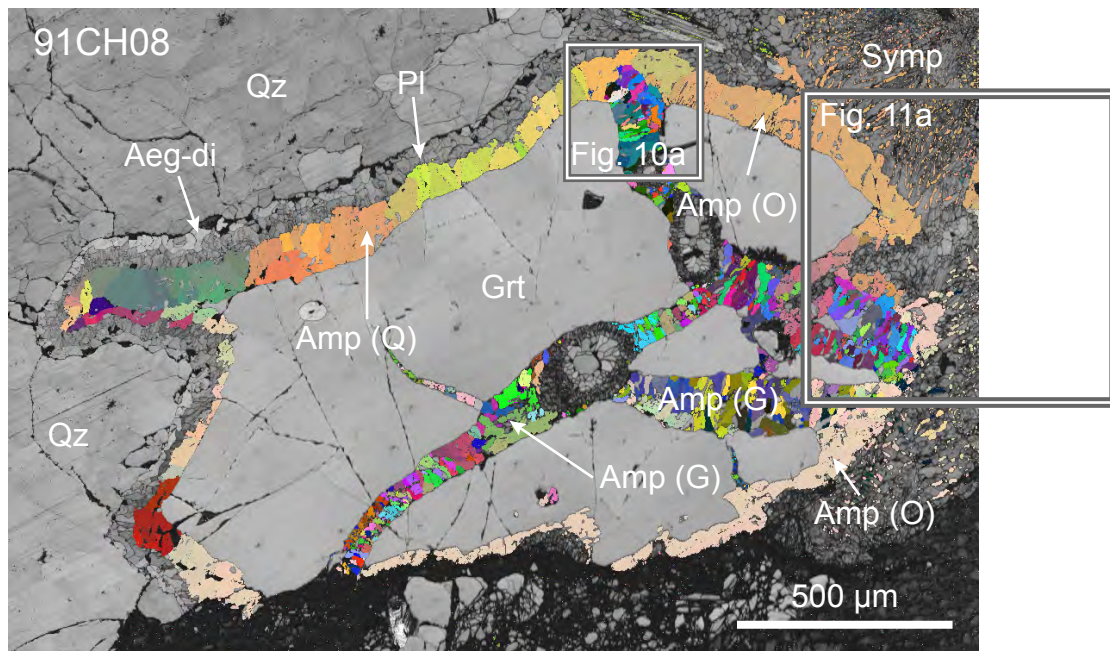

Figure 9. Electron back-scattered diffraction (EBSD) pattern map of Amp (O), Amp (Q), Amp (G), and Amp (S) in an eclogite (91CH08: 2 μm grid step) from the Donghai area, Sulu UHP metamorphic belt.
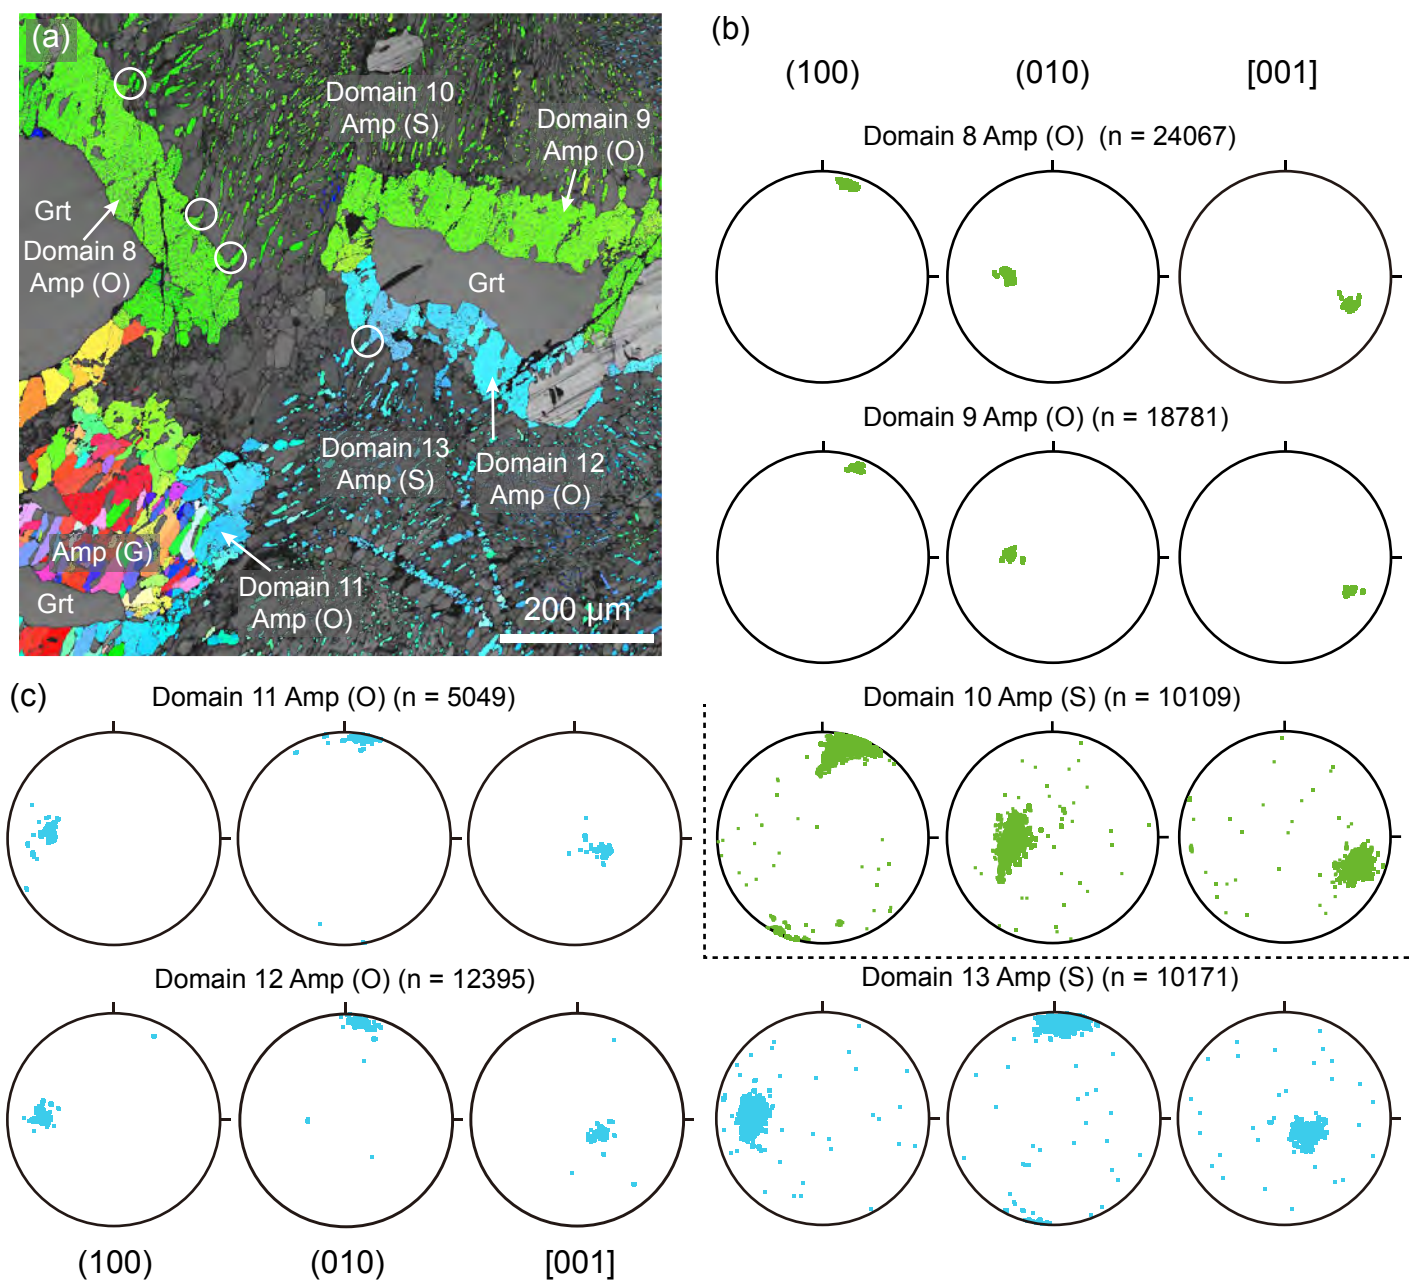

Fig. 9 (Enami and others)
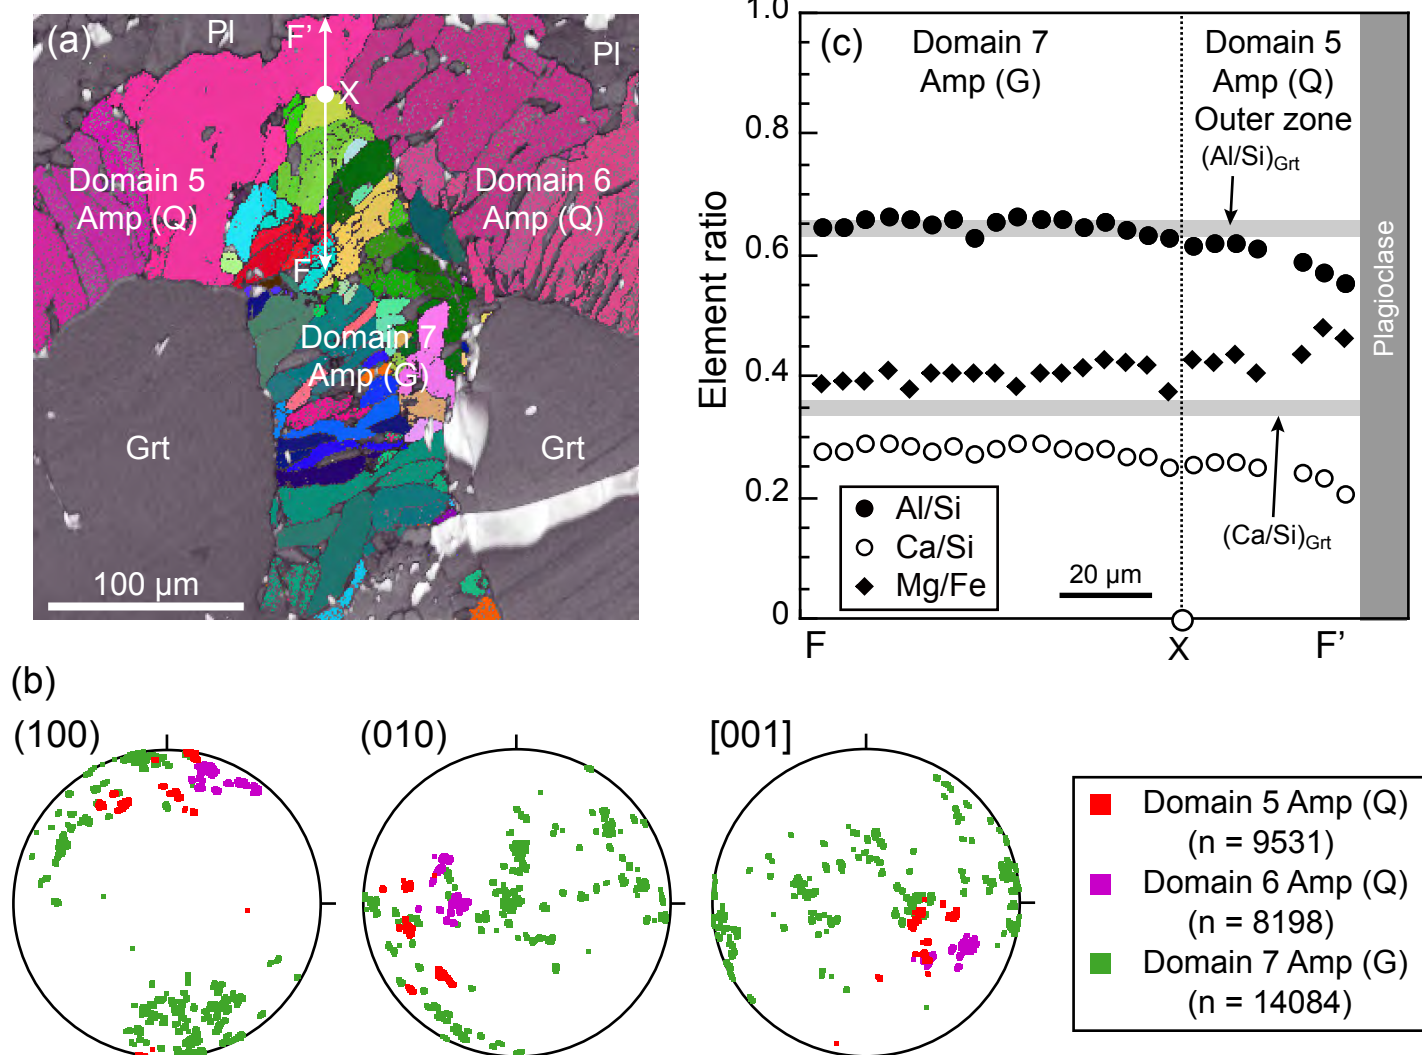

Figure 10. (a) Electron back-scattered diffraction n (EBSD) pattern map (1 μm grid step) of Amp (Q) and Amp (G) in an eclogite (91CH08) from the Donghai area, Sulu UHP metamorphic belt. (b) Equal-area and lower hemisphere projection showing crystallographic orientations of the Amp (Q) and Amp (G) segments. Data n indicates the number of analysis points. (c) Step-scan analysis of the boundary between the Amp (Q) and Amp (G) segments along the line F-F' in Fig. 10a.

Fig. 10 (Enami and others)

Figure 11. (a) Electron back-scattered diffraction (EBSD) pattern map (1 µm grid step) of Amp (O), Amp (G), and Amp (S) in an eclogite (91CH08) from the Donghai area, Sulu UHP metamorphic belt. Equal-area and lower hemisphere projection comparison of crystallographic orientations of the Amp (O) and Amp (S) segments in the sets of (b) domains 8, 9, and 10 and (c) domains 11, 12, and 13. Data n indicates the number of analysis points. Circles in (a) indicate a direct connection between Amp (O) and Amp (S).

univariant lines of Dia-Gr, Coe-Qz, Ab-Jd+Qz, and Al_2SiO_5 phases
were caluculated using THERMOCALC software ver. 3.33 (Powell and
Holland, 1988), internally consistent thermodynamic data set (Holland and
Powell, 1998; updated June 2009), and program
AX_2 (https://filedn.com/lU1GlyFhv3UuXg5E9dbnWFF/TJBHpages/ax.html).
Fig. 12 (Enami and others)

Figure 13. Conceptual diagram of growth scenarios (Models 1 and 2) of retrograde amphiboles in the Donghai eclogites, Sulu UHP metamorphic belt during the exhumation and hydration stage. (a) Eclogite facies and early exhumation stage. (b) Formations of sodic diopside + plagioclase symplectite and crack-filling amphibole [Amp (G)] at the early exhumation and hydration stage, although it is not clear which of these phenomena proceeded first, or if they were nearly simultaneous. (c) Formations of mantle amphibole around garnet [Amp (O) and Amp (Q)] and symplectitic amphibole [Amp (S)] (Model 2). (d1) Initial nucleation of amphibole at the interface between garnet and symplectite of sodic diopside + plagioclase, and subsequent growth of Amp (S) and Amp (O)/Amp (Q). The inner and outer zones of Amp (O) and Amp (Q) grew inward and outward from the initial surface of the garnet (dashed line), respectively (Model 1). (d2) The formation of the inner and outer zones of Amp (O) and Amp (Q) by modification of the chemical composition of their outer parts due to re-equilibration (Model 2).
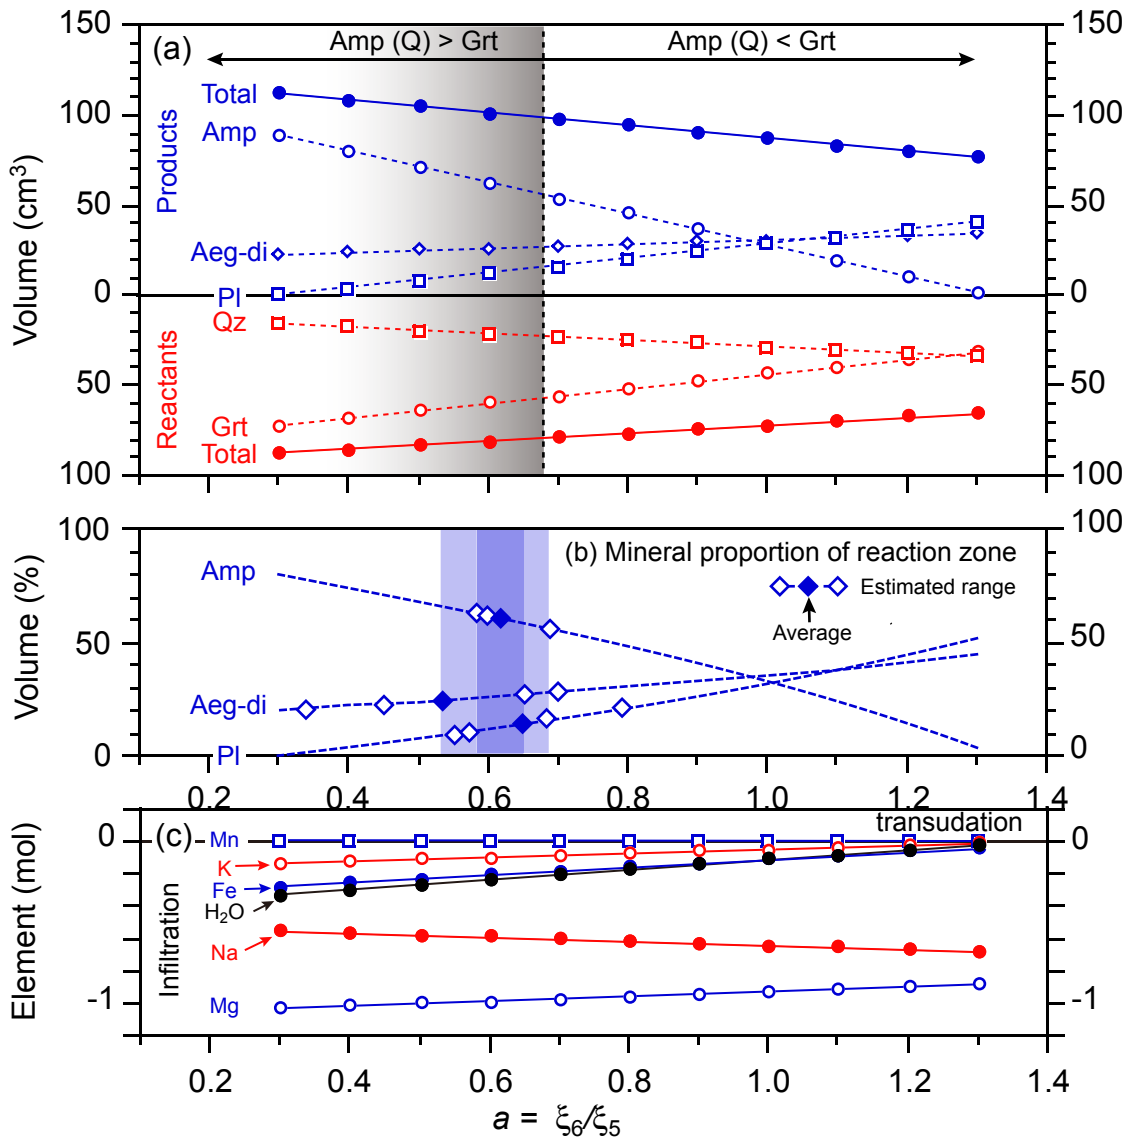

Fig. 13 (Enami and others)

Figure 14. Volume change of minerals [(a) in cm^3 and (b) in %] based on the calculated stoichiometric coefficients of minerals as a function of $a = \xi_6/\xi_5$, where ξ_5 and ξ_6 represent the reaction extents of R5 and R6 in the text, respectively. The mineral volumes were estimated using the molar volumes listed in Table 3. The estimated volume proportions (%) of Amp (Q), aegirine-diopside, and plagioclase in the reaction zone are plotted in Fig. 14b for discussion on the possible range of the parameter a. (c) Stoichiometric coefficients of mobile components as a function of the parameter a.
