28                                                    **ABSTRACT**

29     The new apatite-group mineral pliniusite, ideally $Ca_5(VO_4)_3F$, was found in fumarole deposits at the

30     Tolbachik volcano (Kamchatka, Russia) and in a pyrometamorphic rock of the Hatrurim Complex

31     (Israel). Pliniusite, together with fluorapatite and svabite, forms a novel and almost continuous

32     ternary solid-solution system characterized by wide variations of $T^{5+}$ = P, As and V. In paleo-

33     fumarolic deposits at Mountain 1004 (Tolbachik), members of this system, including the holotype

34     pliniusite, are associated with hematite, tenorite, diopside, andradite, kainotropite, baryte and

35     supergene volborthite, brochantite, gypsum and opal. In sublimates of the active Arsenatnaya

36     fumarole (Tolbachik), pliniusite–svabite–fluorapatite minerals occur with anhydrite, diopside,

37     hematite, berzeliite, schäferite, calciojohillerite, forsterite, enstatite, magnesioferrite, ludwigite,

38     rhabdoborite-group fluoroborates, powellite, baryte, udinaite, arsenudinaite, paraberzeliite, and

39     spinel. At Nahal Morag, Negev Desert, Israel, the pliniusite cotype and V-bearing fluorapatite occur

40     in schorlomite-gehlenite paralava with rankinite, walstromite, zadovite-aradite series minerals,

41     magnesioferrite, hematite, khesinite, barioferrite, perovskite, gurimite, baryte, tenorite, delafossite,

42     wollastonite and cuspidine. Pliniusite forms hexagonal prismatic crystals up to 0.3 mm × 0.1 mm

43     and open-work aggregates up to 2 mm across (Mountain 1004) or grains up to 0.02 mm (Nahal

44     Morag and Arsenatnaya fumarole). Pliniusite is transparent to semitransparent, colorless or whitish,

45     with vitreous lustre. The calculated density is 3.402 g cm$^{-3}$. Pliniusite is optically uniaxial (–), ω =

46     1.763(5), ε = 1.738(5). The empirical formulae of pliniusite type specimens calculated based on 13

47     anions (O+F+Cl) per formula unit are

48     $(Ca_{4.87}Na_{0.06}Sr_{0.03}Fe_{0.02})_{\Sigma 4.98}(V_{1.69}As_{0.66}P_{0.45}S_{0.12}Si_{0.09})_{\Sigma 3.01}O_{11.97}F_{1.03}$ (Mountain 1004) and

49     $(Ca_{4.81}Sr_{0.12}Ba_{0.08}Na_{0.05})_{\Sigma 5.06}(V_{2.64}P_{0.27}S_{0.07}Si_{0.03})_{\Sigma 3.01}O_{12.15}F_{0.51}Cl_{0.34}$ (Nahal Morag). Pliniusite has a

50     hexagonal structure with space group $P6_3/m$, $a = b = 9.5777(7)$, $c = 6.9659(5)$ Å, $V = 553.39(7)$ Å$^3$

51     and $Z = 2$. The structure was solved using single-crystal (holotype) X-ray diffraction, $R = 0.0254$.

52     The mineral was named in honor of the famous Roman naturalist Pliny the Elder, born Gaius Plinius

                                                                                                4

53     Secundus (AD 23–79). It is suggested that the combination of high temperature, low pressure and

54     high oxygen fugacity favors the incorporation of $V^{5+}$ into calcium apatite-type compounds, leading

55     to the formation of fluorovanadates.

56

57          **Keywords**: pliniusite, apatite group, new mineral, calcium fluoride vanadate, fluorapatite,

61

## INTRODUCTION

63

64       The family of apatite-type compounds (apatites, in the common chemical terminology) is

65 huge. It includes more than forty natural members, valid mineral species belonging to the apatite

66 supergroup, and several hundred synthetic phases. This family is well-known and does not need a

67 special presentation, as well as the importance of apatites in natural sciences, modern technologies

68 and human life in general (Kohn et al. 2002).

69       The general simplified formula of apatites is $M_5(TO_4)_3X$ and the crystal chemical formula is

70 $^{IX}M1_2{}^{VII}M2_3(^{IV}TO_4)_3X$ ($Z = 2$), where the Roman numerals indicate the ideal coordination numbers.

71 Apatite-type compounds are hexagonal or pseudo-hexagonal. The space group of the archetype

72 structure of apatite is $P6_3/m$. In minerals of the apatite supergroup, the following components are

73 now known as the species-defining ones: $M = Ca^{2+}$, $Sr^{2+}$, $Ba^{2+}$, $Pb^{2+}$, $Mn^{2+}$, $Cd^{2+}$, $Na^+$, $Y^{3+}$, $La^{3+}$,

74 $Ce^{3+}$, $Nd^{3+}$, $Bi^{3+}$; $T = P^{5+}$, $As^{5+}$, $V^{5+}$, $Si^{4+}$, $S^{6+}$, $B^{3+}$; $X = F^-$, $(OH)^-$, $Cl^-$, $O^{2-}$ (Pasero et al. 2010; The

75 New IMA List... 2021). Based on both chemical and crystal chemical (first of all, ordering of metal

76 cations between different $M$ sites) criteria, five groups have been distinguished within the apatite

77 supergroup: apatite group, hedyphane group, belovite group, britholite group, and ellestadite group.

78 The most widespread in nature and the most numerous apatite-supergroup members belong to the

79 apatite group which includes minerals with pentavalent $T$ constituents ($T^{5+}$ = P, As or V) containing

80 the same prevailing (species-defining) bivalent cation at both the $M1$ and $M2$ sites (Pasero et al.

81 2010).

82       Phosphates and arsenates are the most diverse among apatite-supergroup minerals. In

83 contrast, natural apatite-type vanadates before recently were represented by the only species

84 vanadinite $Pb_5(VO_4)_3Cl$, a member of the apatite group (The New IMA List... 2021). In this paper

85 we describe the second natural apatite-supergroup vanadate, **pliniusite**, ideally $Ca_5(VO_4)_3F$. This

86    new mineral belonging, like vanadinite, to the apatite group, originates from fumaroles of the

87    Tolbachik volcano (Kamchatka, Russia) and from pyrometamorphic rocks of the Hatrurim Complex

88    (Israel).

89        Pliniusite (Cyrillic: плиниусит) was named in honor of the famous Roman naturalist, natural

90    philosopher, author and statesman Pliny the Elder, born Gaius Plinius Secundus (AD 23–79), who

91    wrote the encyclopedic *Naturalis Historia*, which became, in fact, a model for encyclopedias in

92    general. He observed the famous eruption of the Vesuvius volcano in 79 AD and died as a victim of

93    this catastrophic eruption; this kind of volcanic eruptions was named in his memory a Plinian

94    eruption. It is worthy to note that the holotype pliniusite was formed at the Tolbachik volcano during

95    or immediately after the ancient eruption happened about two thousand years ago, approximately in

96    the same time when Pliny the Elder lived.

97        Both the new mineral and its name have been approved by the Commission on New

98    Minerals, Nomenclature and Classification of the International Mineralogical Association (IMA No.

99    2018–031). The type specimens are deposited in the systematic collection of the Fersman

100    Mineralogical Museum of the Russian Academy of Sciences, Moscow under the catalogue numbers

101    96261 (Tolbachik) and 96262 (Hatrurim).

102        Vanadium is an exotic constituent in the majority of apatite-supergroup minerals, whereas many

103    synthetic apatites with various $V^{5+}$ contents at the *T* site are known (White et al. 2005). In this light, we

104    considered of interest to characterize the novel ternary solid-solution system between fluorapatite

105    $Ca_5(PO_4)_3F$, svabite $Ca_5(AsO_4)_3F$ and pliniusite with wide variations of the tetrahedrally coordinated

106    constituents $T^{5+}$ = P, As and V.

107

108               **ANALYTICAL METHODS**

109

110    The chemical composition of the minerals was determined by electron microprobe in two

111    laboratories. The chemical data for samples from Tolbachik were obtained in the Laboratory of

112    Analytical Techniques of High Spatial Resolution, Dept. of Petrology, Moscow State University

113    (MSU) using a Jeol JSM-6480LV scanning electron microscope equipped with an INCA-Wave 500

114    wavelength-dispersive spectrometer, with an acceleration voltage of 20 kV, a beam current of 20

115    nA, and a 3 μm beam diameter. Pliniusite from Hatrurim was examined at the Institute of

116    Geochemistry, Mineralogy and Petrology, University of Warsaw (UW) using a Cameca SX100

117    instrument (WDS mode, 15 kV, 10 nA, 1 μm beam diameter). The reference materials used are as

118    follows (MSU / UW): Na (jadeite / albite), K ($KTiOPO_4$ / orthoclase), Ca ($CaSiO_3$ / diopside), Fe

119    ($FeS_2$ / $Fe_2O_3$), Sr ($SrSO_4$ / $SrSO_4$), Ba ($BaSO_4$ / $BaSO_4$), Si (jadeite / diopside), P ($KTiOPO_4$ /

120    $Ca_5P_3O_{12}F$), V (V / $V_2O_5$), As (GaAs / GaAs), S (ZnS / $BaSO_4$), F ($MgF_2$ / $Ca_5P_3O_{12}F$), and Cl

121    (NaCl / tugtupite). Contents of other elements with atomic numbers higher than that of carbon are

122    below detection limits.

123    The electron microscopic studies of Tolbachik samples were carried out using the same

124    scanning electron microscope at MSU. The samples from Hatrurim were studied using a Phenom

125    XL scanning electron microscope, Faculty of Earth Sciences, University of Silesia, Sosnowiec,

126    Poland.

127    Raman spectra of pliniusite from both localities were collected using a WITec alpha 300R

128    Confocal Raman Microscope (Department of Earth Science, University of Silesia) equipped with an

129    air-cooled solid-state laser (532 nm) and a CCD camera operating at –61°C. An air Zeiss LD EC

130    Epiplan-Neofluan DIC-100/0.75NA objective was used. Raman scattered light was focused on a

131    broadband single-mode fibre with an effective pinhole size of about 30 μm. A monochromator with

132    a 600 gr $mm^{-1}$ grating was used, and the resolution was 3 $cm^{-1}$. The power of the laser at the sample

133    position was *ca*. 30 mW. Integration times of 3 s with an accumulation of 30 scans were chosen. The

134    monochromator was calibrated using the Raman scattering line of a silicon plate (520.7 $cm^{-1}$).

135   Spectra processing such as baseline correction and smoothing was performed using the SpectraCalc

136   software package GRAMS (Galactic Industries Corporation, NH, USA). The fitting of Raman

137   spectra was performed using a Gauss and Lorentz cross-product function, with a minimum number

138   of component bands used for the fitting process.

139       Powder X-ray diffraction (XRD) of the holotype pliniusite was carried out using a Rigaku R-

140   AXIS Rapid II single-crystal diffractometer equipped with a curved image plate detector (Debye-

141   Scherrer geometry, $r$ = 127.4 mm) and Co$K\alpha$ radiation source (rotating anode, 40 kV, 15 mA), with

142   Rigaku VariMax microfocus mirror optics. Imaging plate-to-profile data conversion was performed

143   using osc2xrd software (Britvin et al. 2017).

144       Single-crystal XRD of the holotype pliniusite was carried out using an Xcalibur S CCD

145   diffractometer (Mo$K\alpha$ radiation). A full sphere of three-dimensional data was collected. Data

146   reduction was performed using CrysAlisPro Version 1.171.37.35 (Agilent et al. 2014). The data

147   were corrected for Lorentz and polarization effects. The structure was solved by direct methods and

148   refined with the use of SHELX software package (Sheldrick 2008) on the basis of 416 independent

149   reflections with $I > 2\sigma(I)$ to $R$ = 0.0254 in the frame of space group $P6_3/m$. Trials to lower the

150   symmetry to $P6_3$, $P2_1/m$ or $P$-1 (two latter space groups were reported for synthetic vanadate

151   apatites: see below) did not result in any improvement of the structural model and the $R$ value

152   increased in all these cases. A complete set of crystallographic data can be retrieved from the CIF

153   file attached as the Supplementary Material.

154

155                                    **RESULTS AND DISCUSSION**

156   **Occurrence and mineral associations**

157       The holotype of pliniusite originates from the Tolbachik volcano. This material was collected

158   in July 2017 from paleo-fumarolic deposits of the Southern fumarole field at Mountain 1004, a

159   scoria cone located 20 km SSW of the active volcano Ploskiy Tolbachik. Mountain 1004 is a

160    monogenetic volcano formed as a result of an ancient eruption of Tolbachik, approximately two

161    thousand years ago (Fedotov and Markhinin 1983). All fumaroles at Mountain 1004 are extinct;

162    however, some water-insoluble sublimate minerals are well-preserved to date. The members of the

163    pliniusite–svabite–fluorapatite solid-solution system are associated here with hematite, tenorite,

164    diopside, andradite, kainotropite, and baryte. The secondary mineralization, formed as a result of the

165    supergene alteration of unstable sublimate minerals, is represented by volborthite, brochantite,

166    gypsum and opal.

167         In 2018, pliniusite and V-rich varieties of svabite and fluorapatite were found in the active

168    Arsenatnaya fumarole located at the Second scoria cone of the Northern Breakthrough of the Great

169    Tolbachik Fissure Eruption of 1975–1976. This scoria cone is a monogenetic volcano formed in

170    1975. It is situated 2 km north of Mountain 1004 and demonstrates strong fumarole activity at

171    present day. The Arsenatnaya fumarole is one of the most mineralogically interesting fumaroles at the

172    Tolbachik volcano and, in general, one of the brightest representatives of strongly mineralized

173    oxidizing-type fumaroles in the world. From the mineralogical point of view, this fumarole was

174    characterized, including the data on zonation in distribution of mineral associations, by Pekov et al.

175    (2018) and Shchipalkina et al. (2020). Minerals of the pliniusite–svabite–fluorapatite solid-solution

176    system were found in the deepest and hottest zone of the Arsenatnaya fumarole. It is located at the

177    depth of 3–4 m under day surface; temperatures in the pockets with these minerals measured by us

178    using a chromel-alumel thermocouple were 450–490°C. The associated minerals include anhydrite,

179    diopside, hematite, berzeliite, schäferite, calciojohillerite and subordinate forsterite, enstatite,

180    magnesioferrite, ludwigite, rhabdoborite-group fluoroborates, powellite, baryte, wagnerite (As-

181    bearing variety), udinaite, arsenudinaite, paraberzeliite, and spinel.

182         The cotype material of pliniusite originates from the Nahal Morag canyon area, about 10 km

183    southeast of Arad city, Negev Desert, Israel. The new mineral occurs in pyrometamorphic rocks

184    belonging to the Hatrurim Basin, which is one of the largest unit of the Hatrurim Complex. It is

185 generally recognised that terrigenous-carbonate protolith of the Hatrurim Complex was driven by

186 combustion processes. The geology and origin of the Hatrurim Complex have been discussed

187 previously in detail (Gross 1977; Burg et al. 1999; Novikov et al. 2013; Galuskina et al. 2014). The

188 Nahal Morag canyon crosscuts the central part of the Hatrurim Basin from west to east. In its eastern

189 part there are several cliff-like outcrops (up to 10 m across and up to 1 m in height) of gehlenite-

190 bearing rocks rising along the borders of Nahal Morag. At least in part of them coarse-grained veins

191 (typically 1–3 cm thick) of paralavas occur. Pliniusite was found in vein-like bodies of schorlomite-

192 gehlenite paralava hosted by melilite hornfels. The assemblage of major minerals of the paralavas

193 includes melilite of the gehlenite-alumoåkermanite series, garnet of the andradite-schorlomite series,

194 rankinite, fluorapatite, walstromite, minerals of the zadovite-aradite series, magnesioferrite,

195 hematite, khesinite, barioferrite, and $Fe^{3+}$-enriched perovskite. Pliniusite is typically confined to

196 small oval polymineralic inclusions in rankinite and closely associated with gurimite, baryte,

197 walstromite, tenorite, delafossite, wollastonite, cuspidine and secondary Ca hydrosilicates.

198

199 **General appearance, physical properties and optical data of pliniusite**

200     At Mountain 1004 (Tolbachik), pliniusite and vanadium-bearing varieties of svabite and

201 fluorapatite, which are visually indistinguishable, occur as hexagonal prismatic (from long- to short-

202 prismatic, equant), usually distorted and/or skeletal, cavernous crystals up to 0.3 mm long and up to

203 0.05 mm (rarely up to 0.1 mm) thick. Crystals are isolated or, more commonly, form near-parallel or

204 chaotic clusters (Fig. 1) that are typically combined into open-work aggregates (Fig. 2) up to 2 mm

205 across. These crystals overgrow hematite crusts which cover the surface of the basalt scoria altered

206 by fumarolic gases. In some samples, members of the pliniusite–svabite–fluorapatite solid-solution

207 system occur on diopside aggregates or directly on basaltic scoria. The major forms of pliniusite

208 crystals from Mountain 1004 are the hexagonal prism {10-10} and the hexagonal bipyramid {10-

209 11}; the pinacoid {0001} is common but subordinate and the hexagonal bipyramid {11-21} is minor

11

210 and rare. Some crystals are zoned, with a pliniusite core and svabite peripheral parts, or with a

211 fluorapatite core and a pliniusite rim.

212       At the Arsenatnaya fumarole (Tolbachik), pliniusite and V-rich varieties of svabite and

213 fluorapatite occur inside sublimate incrustations mainly consisting of anhydrite, diopside, hematite,

214 garnets of the berzeliite–schäferite series, calciojohillerite, and V-poor svabite. Pliniusite forms

215 grains up to 0.02 mm.

216       In coarse-grained paralava at Nahal Morag (Hatrurim), pliniusite typically occurs in

217 polymineralic inclusions in rankinite (Figs. 3A and 3B). The new mineral forms grains commonly

218 not exceeding 15 μm in size; rarely, its elongated prismatic crystals up to 40 μm in length are

219 observed (Fig. 3C).

220       Pliniusite is transparent to semitransparent, colorless or whitish, with white streak and

221 vitreous lustre. It does not fluoresce in ultraviolet light. Pliniusite is brittle, has (100) imperfect

222 cleavage (as observed under microscope), and its fracture is uneven. The Vickers microhardness

223 HVIT is 511 kg mm$^{-2}$ [mean of 3 measurements, min = 490, max = 530 kg mm$^{-2}$; max load: 20.00

224 mN; the Nanoindentation Tester (NHT³) Anton-Paar was used], which corresponds to *ca*. 5 in the

225 Mohs hardness scale. Density could not be measured because crystals are small and typically

226 cavernous and aggregates are open-work. Density calculated for the holotype, using the empirical

227 formula and unit-cell volume determined from the single-crystal XRD data, is 3.402 g cm$^{-3}$.

228       Under a plane polarized light microscope, pliniusite (the holotype) is colourless and non-

229 pleochroic. It is optically uniaxial (–), ω = 1.763(5) and ε = 1.738(5) (589 nm). Elongation is

230 negative.

231

232 **Chemical composition**

233       Representative electron-microprobe analyses of minerals of the pliniusite–svabite–

234 fluorapatite solid-solution system from Tolbachik fumaroles and pyrometamorphic rocks of Nahal

235  Morag are given in Table 1. The empirical formulae are calculated on the basis of 13 anions

236  (O+F+Cl) per formula unit.

237      Calcium strongly prevails among $M$ cations in these minerals with > 4.7 Ca atoms per

238  formula unit (*apfu*). The major admixed $M$ cations are Sr and Ba in samples from Nahal Morag (*ca.*

239  0.1 *apfu*: an. 2 and 3 in Table 1) and Na in samples from the Arsenatnaya fumarole (0.10–0.16 *apfu*:

240  an. 13, 15, 17 and 19 in Table 1).

241      The F:Cl ratio significantly varies in minerals from the Arsenatnaya fumarole and Nahal

242  Morag whereas the samples from Mountain 1004 are the F-richest and practically Cl-free.

243      The most interesting chemical feature of the studied minerals is their wide variations in ratios

244  of the major tetrahedrally coordinated constituents $T^{5+}$ = V, P and As,   based on 270 electron-

245  microprobe analyses (Fig. 4). The V-richest samples originate from Nahal Morag (an. 2 in Table 1).

246  At this locality, only As-free pliniusite and fluorapatite were found. In contrast, all studied samples

247  from Tolbachik fumaroles contain As. The V:As:P ratios in Tolbachik samples vary widely, and in

248  some samples the contents of the three $T$ constituents are comparable (an. 5 and 6 in Table 1; Fig.

249  4). In general, the natural ternary solid-solution system among fumarolic fluorapatite, svabite and

250  pliniusite is close to being continuous (Fig. 4).

251      Some samples from all three localities contain distinct amounts of admixed Si and S which

252  sometimes demonstrate coupled substitutions according to the so-called ellestadite scheme: $Si^{4+}$ +

253  $S^{6+} \rightarrow 2T^{5+}$ (up to 0.8 Si+S *apfu*: no. 16 in Table 1).

254      The empirical formulae of two type specimens of pliniusite are as follows:

255      holotype (Mountain 1004, Tolbachik: no. 1 in Table 1):

256  $(Ca_{4.87}Na_{0.06}Sr_{0.03}Fe_{0.02})_{\Sigma4.98}(V_{1.69}As_{0.66}P_{0.45}S_{0.12}Si_{0.09})_{\Sigma3.01}O_{11.97}F_{1.03}$;

257      cotype (Nahal Morag, Hatrurim Basin: #2 in Table 1):

258  $(Ca_{4.81}Sr_{0.12}Ba_{0.08}Na_{0.05})_{\Sigma5.06}(V_{2.64}P_{0.27}S_{0.07}Si_{0.03})_{\Sigma3.01}O_{12.15}F_{0.51}Cl_{0.34}$.

259        The idealized, end-member formula of pliniusite is $Ca_5(VO_4)_3F$, which has CaO 49.70, $V_2O_5$

260    48.35, F 3.37, O=F –1.42, total 100 wt%.

261

262    **Raman spectroscopy**

263        In the Raman spectra of pliniusite (Fig. 5) the main bands are related to vibrations of the

264    $VO_4^{3-}$, $PO_4^{3-}$, $SO_4^{2-}$, $AsO_4^{3-}$ groups. The bands assigned to symmetric ($\nu_1$) and asymmetric ($\nu_3$)

265    stretching vibrations of tetrahedral groups are above 750 $cm^{-1}$. Bands related to bending vibrations

266    ($\nu_2$ and $\nu_4$) occur in the range 300-700 $cm^{-1}$. Bands below 300 $cm^{-1}$ can be assigned to lattice

267    vibrations. The main bands in the Raman spectrum of pliniusite from Nahal Morag and their

268    assignments are [$cm^{-1}$]: 204, 227 (lattice modes), 350 ($\nu_2$ $VO_4^{-3}$), 390 ($\nu_4$ $VO_4^{-3}$), 804, 831 ($\nu_3$ $VO_4^{-3}$)

269    850, 868, 881 ($\nu_1$ $VO_4^{-3}$), 955 ($\nu_1$ $PO_4^{-3}$), 1000 ($\nu_1$ $SO_4^{-2}$) (Frost et al. 2010; Comodi et al. 1999;

270    Galuskin et al. 2015). The Raman spectrum of pliniusite from Mountain 1004 (Tolbachik) shows

271    additional bands that can be assigned to arsenate and phosphate groups at 455 $cm^{-1}$ ($\nu_2$ $AsO_4^{-3}$), 575

272    $cm^{-1}$ ($\nu_4$ $PO_4^{3-}$), 859 $cm^{-1}$ ($\nu_1$ $AsO_4^{3-}$) and 1030 $cm^{-1}$ ($\nu_3$ $PO_4^{3-}$). Accurate bands assignment in the

273    Raman spectra of pliniusite from Tolbachik is hampered by overlapping bands corresponding to

274    vibrations of $VO_4^{3-}$, $AsO_4^{3-}$, $PO_4^{3-}$ and $SiO_4^{4-}$. The bands at 424 $cm^{-1}$ can be attributed to symmetric

275    bending vibrations ($\nu_2$) of $AsO_4^{3-}$ or $\nu_2$ $PO_4^{3-}$ (Comodi et al. 1999; Frost et al. 2015). The absence or

276    very low content of OH groups in pliniusite from both localities are confirmed by Raman

277    spectroscopic data: bands in the region of 3600 – 3700 $cm^{-1}$ are absent.

278

279    **X-ray diffraction data and crystal structure of pliniusite**

280        Powder XRD data of the holotype pliniusite are given in Table 2. Unit-cell parameters of

281    pliniusite obtained from powder data are: $a$ = 9.618(1), $c$ = 6.978(1) Å and $V$ = 559.0(2) Å$^3$. In

282    comparison, those from single-crystal XRD data are: $a$ = 9.5777(7), $c$ = 6.9659(5) Å and $V$ =

283    553.39(7) Å$^3$.

14

284      Although the apatite structure archetype is hexagonal, $P6_3/m$ (Pasero et al. 2010), cation

285      ordering and/or topological distortions can reduce the symmetry. The synthetic compound with the

286      idealized formula $Ca_5(VO_4)_3F$ demonstrates symmetry variations. The hexagonal ($P6_3/m$) form (Aia

287      and Lublin 1966; White et al. 2005) is isostructural with other "ordinary" apatites.  Dong and White

288      (2004) reported monoclinic distortion and space group $P2_1/m$ for $Ca_{10}(VO_4)_6(F_{0.90}O_{0.05\ 0.05})_2$. Baikie

289      et al. (2007) determined space group $P$-1 for $Ca_5(VO_4)_3F$ in which the symmetry lowering is caused

290      by the tilting of $VO_4$ tetrahedra.

291      To check the symmetry of pliniusite (holotype), we tried to solve and refine its structure in

292      space group $P$-1 and obtained the following unit-cell parameters: $a$ = 9.5750(8), $b$ = 9.5767(12), $c$ =

293      6.9645(5) Å, $\alpha$ = 90.039(8), $\beta$ = 89.981(6) and $\gamma$ = 119.956(10)°. Baikie et al. (2007) reported for

294      synthetic triclinic $Ca_5(VO_4)_3F$ the following unit-cell data: $a$ = 9.6987(3), $b$ = 9.6933(3), $c$ =

295      7.0170(2) Å, $\alpha$ = 90.637(3), $\beta$ = 89.172(3) and $\gamma$ = 120.136(2)°. Thus, the deviations of parameters

296      of the synthetic compound from the hexagonal cell are significantly greater than those for pliniusite.

297      The $T$ position in the hexagonal structure of pliniusite transforms to three crystallographically non-

298      equivalent sites in the triclinic model. However, they have site occupancy factors ( s.o.f.) [0.959(3),

299      0.954(3) and 0.963(3); vanadium scattering curve is used] and average $T$–O distances [1.631, 1.634

300      and 1.630 Å, respectively], compared with a $T$ s.o.f. of 0.956(3) ($e_{ref}$ = 21.99) and an average $T$–O

301      distance of 1.631 Å in the hexagonal model (Table 3). Thus, the three $TO_4$ tetrahedra in the triclinic

302      model are equivalent in both occupancy and dimensions. In addition, tetrahedral tilting was not

303      found in this model.

304      Kreidler and Hummel (1970) reported the splitting of reflections (111), (211), (202) and

305      (213) (indices are given for the hexagonal setting) in the powder XRD pattern of synthetic

306      $Ca_5(VO_4)_3F$ as an indicator of the symmetry lowering from hexagonal to monoclinic. Our powder

307      XRD pattern of pliniusite (Table 2) does not demonstrate such splitting.

308    Thus, there is no sign of a symmetry lower than hexagonal  for pliniusite, and we assume it

309    adopts space group $P6_3/m$, the most typical structure for apatite-group members.

310    The basic features of the crystal structure of pliniusite (Fig. 6) are common to minerals of the

311    apatite group (Pasero et al. 2010). Calcium cations occupy two sites with different coordination

312    numbers: nine-fold polyhedron (6+3) is centered by $Ca1$ (Wyckoff position $4f$) and seven-fold

313    polyhedron (6+1) by $Ca2$ ($6h$). For the $T(V)$ site the refined number of electrons is 21.99. This is in a

314    good agreement with the chemical composition of the holotype specimen (Table 1). $Ca1$-centred

315    polyhedra share faces to form columns running along the $c$ axis. Adjacent columns are linked by

316    $TO_4$ tetrahedra, thus forming a quasi-framework with the channels along the $c$ axis (White et al.

317    2005) which host $Ca2$ sites in seven-fold coordination and $F^-$ anions located in the centre of the

318    channels in symmetry plane at $z = 0.25$.

319

**Conditions of pliniusite formation**

321    At the Tolbachik volcano, members of the pliniusite–svabite–fluorapatite solid-solution

322    system are fumarolic minerals deposited directly from the gas phase as volcanic sublimates or

323    formed as a result of the interaction between volcanic gas (as an obvious source of V, As, F and Cl)

324    and basalt scoria. The latter way seems more probable taking into account low volatility of Ca in

325    volcanic gases (Symonds and Reed 1993). These minerals crystallized in fumaroles belonging to the

326    oxidizing type in which hot volcanic gas is mixed with atmospheric air that causes high oxygen

327    fugacity (Africano et al. 2005). For active Tolbachik fumaroles it is concluded in the result of both

328    direct determination of gas composition and detailed studies of sublimate minerals (Meniaylov et al.

329    1980; Zelenski et al. 2011; Pekov et al. 2020 and references therein). In the Arsenatnaya fumarole,

330    minerals of the pliniusite–svabite–fluorapatite solid-solution system crystallized at temperatures not

331    lower than 500°C and, based on data published by Meniaylov et al. (1980), not higher than 800°C.

16

332    The mineral assemblage observed in paleo-fumarolic deposits at the Southern fumarole field of

333    Mountain 1004 allows us to suggest the same or similar conditions of formation.

334         At Nahal Morag, the formation of pliniusite in schorlomite-gehlenite paralava (Fig. 3A),

335    which forms veinlets in gehlenite hornfels, is related to the formation of small portions of Ba-, Ti-,

336    P-, V-, Cu-, U- and F-enriched residual melts. This melt, remained after the relatively rapid

337    crystallization of rock-forming minerals of the paralava, gave the specific polymineralic enclaves in

338    rankinite (Fig. 3B) or in interstices between gehlenite and schorlomite crystals (Krzątała et al. 2020).

339    Pliniusite is associated here with Ba- and/or V-bearing minerals, e.g., walstromite $BaCa_2(Si_3O_9)$ and

340    gurimite, $Ba_3(VO_4)_2$ (Fig. 3C), and it is Ba-richer, compared to fumarolic pliniusite from Tolbachik,

341    and is As-free as well (Table 1). The presence of pseudowollastonite in the schorlomite-gehlenite

342    paralava (Seryotkin et al. 2012) indicates that it was formed at temperatures not lower than 1100°C.

343    Pliniusite crystallized from a melt locally enriched in vanadium which could be extracted from

344    underlying phosphorites or, hypothetically, from bitumen contained in a protolith of

345    pyrometamorphic rocks of the Hatrurim Complex.

346         Noteworthily, pliniusite is the second mineral containing both species-defining anions

347    $(VO_4)^{3-}$ and $F^-$, after aradite $BaCa_6[(SiO_4)(VO_4)](VO_4)_2F$ which was also found in paralavas of the

348    Hatrurim Complex (Galuskin et al. 2015).

349    ~~We believe that~~ The temperature of crystallization of pliniusite in the Hatrurim paralava was

350    significantly higher than Tolbachik fumaroles whereas low pressure and high oxidizing potential are

351    common for both mineral-forming systems. We suggest that such conditions are favorable for the

352    incorporation of significant amount of $V^{5+}$ into the $T$ site of calcium apatite-type compounds and in

353    general for the formation of fluorovanadate minerals.

354

355                                    **IMPLICATIONS**

17

356    Our structural data on the fluorapatite–svabite–pliniusite solid-solution system are potentially

357    important for understanding apatite crystal chemistry in both natural and synthetic systems. Ionic

358    radii of tetrahedrally coordinated $V^{5+}$ (0.355 Å) and $As^{5+}$ (0.335 Å) are about twice larger than that

359    of $P^{5+}$ (0.17 Å) (Shannon, 1976). It is recognized that this difference hampers the formation of solid

360    solutions between fluorapatite $Ca_5(PO_4)_3F$ and svabite $Ca_5(AsO_4)_3F$ or pliniusite $Ca_5(VO_4)_3F$.

361    Moreover, the significant difference in the electron structure between vanadium (metal) and

362    phosphorus (non-metal) atoms prevents the formation of the fluorapatite–pliniusite solid solution.

363    Indeed, pliniusite and V-enriched Ca phosphates of the apatite group are extremely rare in nature:

364    they were unknown before the present work. On the other hand, the apatite-type structure is

365    relatively flexible, and the substitution of $P^{5+}$ for larger $As^{5+}$ or $V^{5+}$ in the tetrahedral $T$ sites can be

366    compensated by the distortion of the basic structural unit, a hexagonal ring formed by $TO_4$ terahedra

367    and slightly distorted $Ca$1-centred tricapped trigonal prisms (White et al. 2005, Fig. 6). In synthetic

368    apatites, incorporation of $V^{5+}$ can cause rotation and titling of tetrahedra accompanied by the

369    twisting of $Ca$1-centred prisms (via changing the so-called "twist angle") (Fang et al. 2018).

370    Besides, Boechat et al. (2020) reported the simultaneous expansion of phosphate ions and

371    contraction of vanadate ions in the solid solution which may minimize the crystallographic disorder

372    symmetry distortion and allow more stability to the structure in the whole composition range of

373    solid solution.

374          Pliniusite was formed in two different geological formations characterized by similar

375    physical and chemical conditions (high temperature, low pressure and high oxidizing potential) but

376    with different mechanisms of crystallization. In paralava belonging to the pyrometamorphic

377    Hatrurim Complex, fluorapatite containing <0.2 $(VO_4)^{3-}$ $pfu$ crystallized at early stage while

378    pliniusite with $(PO_4)^{3-}$ < 0.3 $pfu$ crystallized later, probably from the residual V-enriched melt.

379    Temperatures of crystallization of both minerals were not lower than 1100°C, i.e., the temperatures

380    favorable to the formation of the continuous solid solution $Ca_5[(P_{1-x}V_x)O_4]_3F$, with $0 \le x \le 1$ (Deng

18

381     et al. 2015). The significant gap between phosphate and vanadate from Hatrurim paralavas (Fig. 4)

382     is caused by their crystallization from chemically different melts. In contrast, pliniusite of fumarolic

383     origin, though crystallized at definitely lower temperatures (500–800°C), forms a continuous solid-

384     solution system with fluorapatite and svabite in which, however, samples close to the $Ca_5(VO_4)_3F$

385     end member were not found (Fig. 4).

386          Kinetic factors, fluctuations in gas composition and non-equilibrium conditions of

387     crystallization of the fluorapatite–svabite–pliniusite phases in fumaroles (where gas transports some

388     essential constituents) determine the formation of the (metastable?) solid solution with wide

389     compositional variations in tetrahedrally coordinated components. Fluctuations in chemical

390     composition of volcanic gas can be the major factor which determines the chemistry of this solid-

391     solution system. Taking into account this, justly fumarolic systems can be considered as an

392     excellent, probably the best "natural laboratory" for studies of chemical variations and mechanisms

393     of isomorphous substitutions in high-temperature apatites.

499        Nekrasov, A.N. (2011) Pseudolyonsite, $Cu_3(VO_4)_2$, a new mineral species from the Tolbachik

500        volcano, Kamchatka Peninsula, Russia. European Journal of Mineralogy, 23, 475–481.

501  **Figure captions**

502

503  **Figure 1.** SEM/BSE image of crystals of pliniusite (1) on hematite crystal crust (2) with baryte (3).

504  The holotype specimen is from Mountain 1004, Tolbachik volcano, Kamchatka, Russia.

505

506  **Figure 2.** Whitish open-work aggregates of prismatic pliniusite crystals with yellow diopside on

507  crust consisting of iron-black hematite which covers basalt scoria. The holotype specimen is from

508  Mountain 1004, Tolbachik volcano. FOV width: 2.15 mm. Photo: I.V. Pekov and A.V. Kasatkin.

509

510  **Figure 3.** Pliniusite in the cotype specimen from Nahal Morag, Hatrurim Basin, Israel. A – general

511  view of coarse-grained paralava: reddish-brown – andradite-schrolomite series garnet, light yellow-

512  brown – melilite, colourless – rankinite, wollastonite and cuspidine. B – inclusion of Ba- and $V^{5+}$-

513  bearing minerals in rankinite (Rnk); fragment magnified in C is shown in the frame. C – elongated

514  crystals of pliniusite (Pls) in association with walstromite (Wls), gurimite (Gur), tenorite (Tnr),

515  cuspidine (Cus), rankinite (Rnk), wollastonite (Wo), and secondary Ca-hydrosilicates (HSi). B and

516  C are SEM/BSE images of polished sections.

517

518  **Figure 4.** Ratios of major tetrahedrally coordinated constituents ($T$) in minerals of the pliniusite–

519  svabite–fluorapatite solid-solution system.

520

521  **Figure 5.** Raman spectra of pliniusite from (a) Nahal Morag, Hatrurim Basin (cotype) and (b)

522  Mountain 1004, Tolbachik volcano (holotype).

523

524  **Figure 6.** Crystal structure of pliniusite (space group $P6_3/m$) projected down the $c$-axis. Black lines

525  outline the unit cell.

561

562 Pliniusite, fluorapatite and svabite are labeled as Pln, FAp and Svb, respectively. The localities are labeled as: Mt. 1004 – Southern fumarole

563 field at Mountain 1004, Tolbachik volcano (Nos. 1, 4–7, 9, 10, 12); N. M. – Nahal Morag, Hatrurim Basin (Nos. 2, 3, 15, 17); Arsen. –

564 fumarole Arsenatnaya, Tolbachik (Nos. 8, 11, 13, 14, 16, 18, 19).

565 $\Sigma M$ = Na+K+Ca+Sr+Ba+Mn+Fe, $\Sigma T$ = Si+P+V+As+S+Cr. Empty cell means that the content of a constituent is below the detection limit

566 and dash means 0.00 *apfu* (for minor admixtures). Nos. 1 and 2: average values for eight and five spot analyses, respectively; ranges are

567 given in parentheses.

568 **Table 2.** Powder X-ray diffraction data ($d$ in Å) of the holotype pliniusite.

569    *For the calculated pattern, only reflections with intensities ≥1 are given; **calculated with the unit-
570    cell parameters from single-crystal XRD data. The strongest reflections are marked in bold.
