22   **Abstract**

23   The unconformity-related uranium (URU) deposits in the Proterozoic Athabasca

24   Basin (Canada) represent the richest and one of the most important uranium endowments

25   in the world. Most of the URU deposits are associated with pre-existing graphitic

26   basement faults that were reactivated after the formation of the basin. These graphite-rich

27   structures have been widely used as a vector for exploration, but the nature of the

28   association of the URU deposits with graphitic basement faults has been debated for over

29   four decades. Proposed roles of graphite include: 1) as a direct reducing agent to reduce

30   U^{6+} to U^{4+} and precipitate uraninite, 2) as a precursor of hydrocarbons (mainly CH_4)

31   produced in situ or nearby and then used as a reducing agent for uraninite precipitation; 3)

32   as a precursor of hydrocarbons produced at depth that were remobilized to the site of

33   mineralization and acted as a reducing agent for uraninite precipitation; and 4) as a

34   lubricant facilitating faulting and fluid flow that led to uranium mineralization. This

35   paper uses the Phoenix uranium deposit in the southeastern Athabasca Basin as a case

36   study to address these uncertainties. Petrographic studies indicate that there is no direct

37   contact between graphite and uraninite at microscopic scales and the content of graphite

38   in the graphitic metapelite along the ore-controlling WS Shear Zone does not show a

39   systematic change with the distance from the unconformity surface. Raman spectroscopic

40   studies of graphite suggest that the degree of structural disorder of graphite, expressed by

41   various parameters related to the D bands and G band ratios, does not change

42   systematically with the distance from the unconformity surface either. The minor

43   irregularities in these parameters near the unconformity are better explained by

44   paleo-weathering related to the unconformity and/or diagenetic processes than by

45   hydrothermal activity related to uranium mineralization. Based on these observations and

46   interpretations, the role of graphite as an in situ reducing agent, either directly or as a

47   provider of hydrocarbons, is discounted. It is proposed that hydrocarbons derived from

48   graphite at depth, tapped by episodic reactivation or seismicity of the basement faults that

49   was facilitated by graphite as a lubricant, were responsible for URU mineralization.

51   deposits, Phoenix, Athabasca Basin

52
53   **Introduction**

54   The Proterozoic Athabasca Basin, located in northern Saskatchewan and Alberta,

55   Canada (Fig. 1a), is known for its high-grade, large-tonnage uranium deposits located

56   near the unconformity between the flat-lying sedimentary rocks in the basin and strongly

57   deformed and metamorphosed rocks in the basement (Hoeve and Sibbald 1978; Jefferson

58   et al., 2007; Kyser and Cuney 2015). These deposits, known as the unconformity-type or

59   unconformity-related uranium (URU) deposits, are spatially associated with reactivated

60   basement faults crosscutting and/or reversely displacing the unconformity surface, and

61   most of the ore-controlling faults are developed in graphite-rich lithologies (Hoeve and

62   Sibbald 1978; Jefferson et al. 2007; Kyser and Cuney 2015). As such, graphite has been

63   generally considered to have played an important role, either directly or indirectly, in the

64   formation of the URU deposits (Hoeve and Sibbald 1978; Hoeve and Quirt 1984; Kyser

65   et al. 1989; Landais et al. 1993; Alexandre et al. 2005; Yeo and Potter 2010; Dargent et al.

66   2015; Potter and Wright 2015; Pascal et al. 2016a, b; Martz et al. 2017, 2019).

67   Consequently, graphite-rich zones interpreted from geophysical surveys, particularly

68   electromagnetic (EM) conductors, have been widely used to guide uranium exploration in

69   the Athabasca Basin for the last several decades (Hoeve and Sibbald 1978; Jefferson et al.

70   2007; Kerr 2010; Yeo and Potter 2010; Marlatt and Kyser 2011; Potter and Wright, 2015).

71   However, the nature of the relationship between graphite and URU mineralization

72   remains unclear, which affects the reliability of the exploration model.

73   In the original "diagenetic-hydrothermal' model of Hoeve and Sibbald (1978),

74   diagenetic fluids from the basin penetrated into the basement and reacted with graphite to

75   produce CH_4 and CO_2 that then flowed upward along facture zones toward the

76   unconformity surface, where U^{6+} carried by oxidizing basinal fluids was reduced by the

77   upwelling CH_4 and uraninite was precipitated. This model is supported by the presence of

78   blebs (or "buttons") of amorphous carbon or hydrocarbons (bitumen) in many of the

79   URU deposits (Hoeve and Sibbald 1978; Hoeve and Quirt 1984; Leventhal et al. 1987;

80   Kyser et al. 1989; Landais et al. 1993). However, based on comparison of C isotopes

81   between graphite and bitumen, Leventhal et al. (1987) and Kyser et al. (1989) suggested

82   that the bitumen found in the ores could not be derived from the nearby graphite.

83   Although the similarity in C isotopes between graphite and bitumen may be explained by

84   the formation of hydrocarbons through reaction between graphite and H_2 produced from

85   radiolysis of water (Dubessy et al. 1988), such a mechanism would not have operated

86   until there were significant amounts of uranium accumulation, i.e. post-mineralization

87   (Kyser et al. 1989). Wilson et al. (2007) also suggested that the bitumen associated with

88   URU deposits were introduced after mineralization, and inferred that the hydrocarbons

89   were sourced from the Douglas Formation in the Athabasca Basin based on biomarkers.

90   McCready et al. (1999) and Annesley et al. (2001), on the other hand, presented

91   petrographic and geochemical evidence suggesting that there is more than one generation

92   of hydrocarbons in the URU deposits and that some were emplaced before mineralization,

93   implying that hydrocarbons may have played a role in mineralization. None of the

94   above-mentioned studies preclude the possibility that hydrocarbons derived from the

95   basement at depth (instead of from graphite in the immediate host rocks) were the

96   reducing agents responsible for URU mineralization (Dargent et al. 2015; Martz et al.

97   2017, 2019; Branquet et al. 2019). Fluid inclusions containing hydrocarbons (especially

98   CH_4) as well as hydrogen gas (H_2) have been reported in many URU deposits (Derome et

99   al. 2003; Pascal et al. 2016b; Richard 2017; Chi et al. 2018a; Martz et al. 2019), but the

100   timing of entrapment of these gases relative to mineralization remains uncertain.

101   It has also been proposed that some U^{6+} in the ore-forming fluid may have been

102   reduced to U^{4+} directly by graphite (Alexandre et al. 2005). However, this mechanism is

103   not supported by a spatial association between graphite and uraninite at microscopic

104   scales, as would be expected if graphite is used as reductant to precipitate uraninite (Yeo

105   and Potter 2010). Furthermore, graphite has been shown to be a much less efficient

106   reductant than H_2 and CH_4 (Dargent et al. 2015) and some URU deposits are hosted in

107   non-graphitic lithologies, e.g., sericite-chlorite schist at the Centennial deposit, paragneiss

108   at the Cluff Lake deposit, and quartzite and calc-meta-arkose at the Raven and Horseshoe

109   deposit (Yeo and Potter 2010). Because of the controversies outlined above, some authors

110   suggest that the main reducing agents for URU mineralization are neither graphite nor

111   hydrocarbons derived from it, but rather non-carbon based species such as Fe^{2+} and H_2S

112   (Komninou and Sverjensky 1996; Yeo and Potter 2010; Ng et al. 2013), and graphite may

113   simply serve as a lubricant facilitating basement fault reactivation and subsequent fluid

114   flow (Kyser et al. 1989; Yeo and Potter 2010).

115   Regardless of the controversies regarding the origins of the hydrocarbons and their

116   roles in URU mineralization, graphite in the vicinity of several URU deposits is more

117   altered than graphite in the country rocks, as manifested by depletion or "consumption",

118   corrosion and/or degradation of graphite at the site of mineralization (Hoeve and Sibbald

119   1978; Hoeve and Quirt 1984; Leventhal et al. 1987; Kyser et al. 1989; Wang et al. 1989;

120   Landais et al. 1993; Yeo and Potter 2010; McCready et al. 1999; Annesley et al. 2001;

121   Pascal et al. 2016a, b). However, the timing of these graphite alteration and destruction

122   events are poorly constrained, ranging from pre-Athabasca Basin to post-mineralization

123   (Dubessy et al. 1988; McCready et al. 1999; Annesley et al. 2001; Pascal et al. 2016a, b).

124   Further studies of graphite from URU deposits, especially the temporal and spatial

125   relationships between graphite alteration, hydrocarbon development and uranium

126   mineralization are therefore warranted.

127   Raman spectroscopy has been widely used to address various Earth science

128   problems (Dubessy et al. 2012; Chou and Wang 2017) and has been found particularly

129   useful in studying the structure of graphite and related geological conditions (Landais et

130   al. 1993; Beyssac et al. 2002, 2003; Lahfid et al. 2010; Martz et al. 2017). Crystalline

131   graphite sensu stricto is made of ABAB stacking of graphene layers consisting of

132   hexagonal unit cells constructed by carbon atoms, whereas the more general term

133   'graphitic carbon' include those that have amorphous-like or turbostratic structures

134   (Beyssac and Rumble 2014). It has been well documented that the graphitization process

135   with increasing temperature is associated with increasing order of crystal structure

136   (Beyssac et al. 2002, 2003; Lahfid et al. 2010), and graphite can be degraded at lower

137   temperatures in the presence of fluids (Wang et al. 1989; Landais et al. 1993). Graphitic

138   carbons with different crystallinity or order of crystal structure have different Raman

139   spectroscopic characteristics (Beyssac et al. 2002, 2003; Lahfid et al. 2010), and therefore

140   Raman spectroscopic study may reveal the conditions of graphite formation and/or its

141   modification.

142   In this paper, we present a case study of graphite from the Phoenix uranium deposit

143   located in the southeastern Athabasca Basin (Fig. 1a; Kerr 2010; Wang 2016; Wang et al.

144   2018) in order to address the above-discussed problems regarding the roles of graphite in

145   URU mineralization. The Phoenix deposit has an estimated resource of 71.3 million

146   pounds of U_3O_8 at an average grade of 19.13 wt.% U_3O_8 (Roscoe 2014), making it one of

147   the richest and largest uranium deposits in the world (IAEA 2016). Graphite-bearing

148   samples with varying distances from the ore zone and/or unconformity were collected for

149   petrography and Raman spectroscopy. Different generations of graphite were recognized

150   and their relative timing with regard to other minerals were established based on

151   crosscutting relationships observed in the hand samples and thin sections. Minor fluid

152   inclusions associated with graphite were examined with microthermometry. The contents

153   of graphite in the rocks and various parameters indicating the graphite crystallinity were

154   estimated from the Raman spectra. Correlation of these parameters with the distance from

155   the ore zone and/or unconformity was then used to illustrate the role of graphite in the

156   formation of the Phoenix uranium deposit and broader association between graphite and

157   URU deposits in the Athabasca Basin. Finally, the results were integrated with previous

158   studies to illustrate how graphitic faults may have controlled fluid flow and the linkage

159   between ore fluids and the sources of reducing agents for URU mineralization.

160

161   **Regional and local geology**

162   The Paleoproterozoic to Mesoproterozoic Athabasca Basin contains mainly

163   siliciclastic rocks (the Athabasca Group) resting unconformably on Archean to

164   Paleoproterozoic basement (Ramaekers et al. 2007). The Athabasca Group is divided into

165   four unconformity-bounded sequences, which are, from bottom to top, the sandy to

166   conglomeratic Fair Point Formation (sequence 1), the quartz-arenitic Read, Smart and

167   Manitou Falls formations (sequence 2), the pebbly to sandy Lazenby Lake and mud-rich

168   Wolverine Point formations (sequence 3), and the pebbly to sandy and conglomeratic

169   Locker Lake, sandy Otherside, mud-rich Douglas, and dolomitic Carswell formations

170   (sequence 4) (Ramaekers et al. 2007). The western part of the basin is underlain by

171   basement rocks belonging to the Taltson magmatic zone and the Rae Province, and the

172   eastern part is underlain by the Hearne Province, which is bounded in the east by the

173   Trans-Hudson Orogen (Fig. 1a; Card et al. 2007). The Hearne Province consists of, from

174   west to east, the Virgin River, Mudjatik, Wollaston and Peter Lake domains (Fig. 1a). The

175   Wollaston Domain, which underlies the Phoenix deposit, is composed of

176   Paleoproterozoic metasedimentary rocks of the Wollaston Supergroup and Archean

177   granitoid gneisses, with minor amounts of mafic to felsic intrusions of unknown ages

178   (Annesley et al. 2005; Card et al. 2007; Yeo and Delaney 2007). Most of the basement

179   rocks were strongly deformed, forming tight to isoclinal northeast-trending doubly

180   plunging folds and thrust structures and subject to upper amphibolite- to lower

181   granulite-facies metamorphism during the Trans-Hudson orogeny (Annesley et al. 2005;

182   Card et al. 2007; Yeo and Delaney 2007).

183   The Phoenix uranium deposit is situated in the southeastern Athabasca Basin,

184   among a number of URU deposits distributed along the Mudjatik – Wollaston Transition

185   Zone (Fig. 1a). The mineralization occurs at the unconformity contact and is associated

186   with a basement fault zone called the WS Shear Zone (Figs. 1b and c). The sedimentary

187   rocks above the unconformity are conglomerates and sandstones of the Read Formation

188   and the overlying Manitou Falls Formation (Bosman and Korness 2007; Fig. 1c). The

189   basement rocks comprise graphitic and non-graphitic pelitic gneiss, semipelitic gneiss,

190   quartzite, and minor pegmatitic gneiss (Figs. 1b and c). Some of the pelitic units contain

191   garnet, cordierite and sillimanite indicative of upper amphibolite- to lower

192   granulite-facies metamorphism. The pelitic gneiss is referred to as metapelite in local

193   geological reports (e.g., Roscoe 2014; Figs. 1b and c), and the same term is adopted in

194   this paper. The WS Shear Zone strikes northeast, dips moderately to the southeast (Figs.

195   1b and c), and crosscuts the unconformity displaying a minor reverse offset. The fault

196   developed between graphitic metapelite and garnetiferous metapelite in the footwall, and

197   metapelite, pegmatitic rocks and garnetiferous metapelite in the hanging wall (Figs. 1b

198   and c). A massive quartzite body, characterized by a prominent ridge of the unconformity

199   surface (basement high), is situated to the west of the garnetiferous metapelite in the

200   footwall (Figs. 1b and c). It is worth noting that, in contrast to the conventional

201   interpretation of quartzite and graphitic metapelite as derived from metamorphism of

202   sedimentary rocks, the quartzite and the graphite in the graphitic metapelite and the study

203   area have been alternatively interpreted as of hydrothermal origin (Card 2012, 2014;

204   Adlakha and Hattori 2021). In this paper, the terms of 'quartzite' and 'graphitic

205   metapelite' are used without considering their origins, as in Wang et al. (2018). The top 3

206   to 10 m of the basement rocks immediately below the unconformity were subject to

207   paleo-weathering (Kerr 2010).

208   The orebodies of the Phoenix deposit occur as shallowly dipping lenses mostly

209   hosted by the lowermost Athabasca Group above the unconformity, underlain by

210   graphitic metapelite and the WS Shear Zone (Figs. 1c, 2a). Parts of the orebodies extend

211   into the basement for a few meters, and minor discontinuous, thin ore lenses are

212   developed along steeply dipping subsidiary faults associated with the WS Shear Zone.

213   The ores are composed of uraninite and variable amounts of kaolinite, tourmaline

214   (magnesio-foitite), illite and minor sulfides (mainly pyrite) (Wang et al. 2018). The

215   mineralized zones are surrounded by a desilicification and clay alteration halo (Fig. 2a)

216   characterized by disintegration of sandstone into loose grains and development of

217   pervasive clay-sized magnesio-foitite, kaolinite and illite, and minor amounts of chlorite.

218   Silicification, manifested as quartz cementation, especially drusy quartz filling fractures

219   and dissolution vugs, is widely developed in the sandstone outside the desilicification and

220   clay alteration halo, and drusy quartz is also locally developed in the basement (Wang et

221   al. 2018).

222

223   **Sampling and analytical methods**

224   A total of 45 samples containing graphite were collected from six drill cores (Fig.

225   1b and c; Table 1). Most samples are from the graphitic metapelite (Fig. 2b) of the WS

226   Shear Zone, and some from the hanging wall and footwall, with variable distances from

227   the orebodies and/or unconformity. A few samples were collected from a drill core

228   (WR-412; Fig. 1b) that does not intersect the WS Shear Zone for comparison. In addition

229   to graphitic metapelite, samples with quartz veins that contain graphite and crosscut

230   graphitic metapelite (Fig. 2c) and pegmatite crosscut by graphite filling fractures (Fig. 2d)

231   were also examined. The strategy of sampling was to identify different generations of

232   graphite and to evaluate if there are systematic variations of properties and amounts of

233   graphite dispersed in the graphitic metapelite along the WS Shear Zone with increasing

234   distance from the unconformity surface or orebodies, by examining samples intersected

235   by different drill cores at different depths. Samples collected from the hanging wall and

236   footwall also allowed evaluation of lateral changes of graphite properties away from the

237   graphitic fault zone.

238   The samples were made into polished thin sections for petrographic and Raman

239   spectroscopic studies. Optical examination of polished thin sections was conducted on an

240   Olympus BX51 petrographic microscope equipped with both transmitted and reflected

241   light attachments. Different generations of graphite were identified and their relative

242   timing with respect to the paragenetic sequence established by Wang et al. (2018) was

243   evaluated based petrographic observations. The content of graphite was estimated by

244   moving the thin section randomly and point-counting 250 points (at the crosshair); only

245   the graphite exposed on the surface (detected by reflected light) was counted for

246   consistency.

247   Raman spectroscopic analyses were performed using a Renishaw RM2000 laser

248   Raman spectrometer at the Geofluids Laboratory of the University of Regina. The

249   excitation laser (Spectra-Physics) has a wavelength of 514.5 nm, the grating was set to

250   1,800 gr/mm, and the objective was ×50 with long working distance. Each generation of

251   graphite was examined for their Raman spectroscopic characteristics, and the most

252   abundant type of graphite that is dispersed in graphitic metapelite was studied on a 50

253   points per thin section basis. As the Raman spectra vary with the orientation of the crystal

254   (Wang et al. 1989; Beyssac et al. 2002, 2003), the average of the 50 measurements were

255   taken to represent the Raman characteristics of the individual sample, while the standard

256   deviation reflects uncertainties as well as variation of crystal orientations. The laser was

257   kept at low power (0.15 mW) to minimize the effect of heat induced by laser on graphite

258   structure (Beyssac et al. 2003). Each spot was analyzed for 60 seconds (six acquisitions,

259   10 seconds each) in the range from 1000 to 3500 cm^{-1}, which covers all peaks of

260   graphite.

261   The Raman spectra in the first-order region (1100 – 1800 cm^{-1}) are characterized

262   by their peak location, intensity and area as well as several different combinations of

263 these parameters related to the degree of disorder of graphite crystal structure (Beyssac et

264 al. 2002, 2003; Lahfid et al. 2010). There are two types of bands in this region: graphite

265 (G) and defect (D) bands, the latter including four bands labelled D1 to D4 (Lahfid et al.

266 2010). The G band and D1 band have a prominent peak at $1580 - 1600$ cm^{-1} and 1350

267 cm^{-1}, respectively, whereas D2 (1620 cm^{-1}) occurs as a right shoulder of the G band, D4

268 (1200 cm^{-1}) as a left shoulder of the D1 band, and D3 is superimposed on the trough

269 between D1 and G (Lahfid et al. 2010). In perfectly crystalline graphite, only the G band

270 is present (Beyssac et al. 2003). The areas of the individual bands were calculated using

271 the Lorentzian peak-fitting profile (Lahfid et al. 2010) provided in the WiRE 3.4 software.

272 The following parameters were used to describe the degree of disorder of graphite: 1)

273 D1/G; 2) D/G, where D is the total of D bands; 3) RA1 = (D1+D4)∕(D1+D2+D3+D4+G);

274 and 4) R2 = D1 / (G+D1+D2), all as area ratios.

275

276 **Results**

277 **Different generations of graphite and their petrographic characteristics**

278 Four generations of graphite (Gr1 – Gr4) were recognized in the samples examined.

279 Two of them (Gr1 and Gr3) were discernable from the hand samples (Fig. 2), and the

280 other two (Gr2 and Gr4) were distinguished in thin sections (Fig. 3). Gr1 developed in

281 the graphitic metapelite, as flakes oriented along the schistosity (Figs. 2b, c, 3a). Gr2

282 occurs as inclusions in quartz replacing or cementing metapelite (Fig. 3e). Gr3 developed

283 within fractures in graphitic metapelite (Fig. 2b) and quartz veins (Fig. 2c) or pegmatitic

284   rocks (Fig. 2d) that crosscut graphitic metapelite. Gr3 is inferred to be later than Gr2 on

285   the basis that Gr3 crosscuts the quartz coeval with that enclosing Gr2. Gr4 is not actually

286   graphite, but rather amorphous carbonaceous matter that occurs in interstitial space in the

287   sandstones and as rare inclusions in drusy quartz (Fig. 3g). Among the four generations of

288   graphite, Gr1 is volumetrically the most abundant and best developed in the metapelite,

289   whereas the others are scattered and locally developed in various lithologies including

290   quartzite and pegmatites. No uraninite was found in the samples collected for graphite

291   study from the Phoenix deposit, so no petrographic relationships between graphite and

292   uraninite could be observed. However, microscopic and SEM-EDS examination of a

293   mineralized sample from Gryphon Zone (about 2.5 km west of Phoenix) indicates that

294   uraninite is not spatially associated with graphite; even when they occur close to each

295   other locally, they are rarely in contact (Fig. 3h).

296   Gr1 is dispersed in metapelite and is mostly flake-shaped or tabular (Fig. 3a), but

297   locally it shows more equant and irregular shapes (Fig. 3b) in samples close to the

298   unconformity. The width of Gr1 flakes vary from 10 to 200 μm. Under reflected light,

299   Gr1 grains have relatively high reflectance in the central part of individual crystals,

300   relatively low reflectance near the edge (Fig. 3c), and the average reflectance appears to

301   be relatively low for crystals in samples close to the unconformity. Micron- to

302   sub-micron-sized pits (micro-pits), similar to the "hollow points" reported for the Cigar

303   Lake uranium deposit by Wang et al. (1989), are locally developed in Gr1 in samples

304   close to the unconformity (Fig. 3d). Gr2 is round-shaped and occurs as aggregates or

305   individual inclusions (blebs) enclosed within quartz that replaced graphitic metapelite

306   (Fig. 3e). The size of individual grains or blebs range from a few to tens of microns. The

307   reflectance is relatively high (even under quartz) and fairly homogeneous (Fig. 3e insert).

308   Gr3 shares some similarities with Gr1 but it is generally more equant-shaped,

309   coarser-grained and of higher reflectance than Gr1 (Fig. 3 f). It occurs in microfractures

310   or interstitial space, and is commonly associated with pyrite (Fig. 3f). Gr4 in growth

311   zones in drusy quartz (Fig. 3g) is rare and characterized by irregular shapes and very low

312   reflectance.

313   **Raman spectroscopic characteristics of different generations of graphite**

314   The Raman spectra of Gr1 grains are characterized by a prominent G band at 1582

315   cm^{-1}, with or without a D1 band at 1356 cm^{-1} and a D2 band at 1620 cm^{-1} (Fig. 4a),

316   suggesting variable degrees of structural disorder. Gr1 that has micro-pits shows more

317   intense D bands than Gr1 without micro-pits (Fig. 4b), and Gr1 within the micro-pits

318   shows stronger D bands than Gr1 outside the micro-pits (Fig. 4c). All Gr2 grains show a

319   sharp G band with no D bands in the first order region (Fig. 4d), indicating a very high

320   degree of structural order. Gr3 mostly has similar Raman spectra as Gr2, i.e., only the G

321   band and not D bands in the first order region, but some show a minor D1 band (Fig. 4e).

322   The Raman spectra of Gr4 are characterized by a dominant D1 band at ~1350 cm^{-1} and a

323   broad band combining G and significant D2 at ~1600 cm^{-1} (Fig. 4f), and some spectra

324   also show a broad D3 band at 1500 cm^{-1}, all indicating a very high degree of structural

325   disorder.

Fluid inclusions associated with Gr2

326

327   Fluid inclusions are locally associated with Gr2 blebs (Fig. 5). Some blebs contain

328   a visible fluid phase composed of CO_2, CH_4 and N_2 as detected by Raman spectroscopy

329   (Fig. 5a), and others contain CH_4 and N_2 even though no fluid phase was discernable (Fig.

330   5b). In some healed fractures, Gr2 blebs occur with CH_4 and aqueous inclusions, forming

331   a fluid inclusion assemblage (FIA; Goldstein and Reynolds 1994) (Fig. 5c). An aqueous

332   liquid is attached to some of the Gr2 blebs (Fig. 5c). The CH_4 inclusions are monophase

333   at room temperature and nucleated a liquid phase when cooled to temperatures between

334   -100 and -170 °C (Fig. 5d). In one FIA, the CH_4 inclusions show homogenization (to

335   vapor) temperatures from -165.0 to -120.4 °C (n = 22), and the aqueous inclusions have

336   ice-melting temperatures from -0.9 to -2.6 °C, with calculated salinities from 1.8 to 4.3

337   wt.% NaCl equivalent, and homogenization (to liquid) temperatures from 106 to 276 °C

338   (n = 9). In another FIA, the CH_4 inclusions show homogenization (to vapor) temperatures

339   from -113.1 to -98.5 °C (n = 5). Fluid pressures estimated from the isochores of the CH_4

340   inclusions, calculated with the equation of Setzmann and Wagner (1991) in the FLUIDS

341   software of Bakker (2003), range from 3 to 140 bars for the temperature range from 106

342   to 276 °C.

Graphite abundance and spatial variation

343

344   The volumetric abundance of graphite (mainly Gr1) in the samples studied, based on

345   250 counts in each thin section, range from 0 to 9.2% (n = 45; Table 1). The samples are

346   divided into three types: 1) graphitic metapelite in the WS Shear Zone; 2) hanging wall and

347   footwall of the WS Shear Zone; and 3) drill core (WR-412) that is located ~500 m away

348   from the WS Shear Zone (Fig. 1b). The diagrams correlating the abundance of graphite

349   with the vertical distance of the sample from the unconformity surface (Fig. 6) show that

350   there is no systematic variation over a distance of ~200 m (Fig. 6a). There is a trend of

351   decreasing graphite abundance toward the unconformity in the top 10 – 50 m of the

352   basement, but no trends of graphite abundance with depth are discernable if the top 10 m

353   (shaded area in Fig. 6) is excluded.

Degree of order of graphite (Gr1) structure and spatial variation

355   The parameters of Raman spectra of graphite (Gr1) that indicate the degree of

356   crystal structural disorder, i.e., D1/G, D/G, RA1 = (D1+D4) ⁄ (D1+D2+D3+D4+G), and

357   R2 = D1 / (G+D1+D2) (Table 1; Supplementary Table 1), are plotted against the distance

358   from the unconformity surface (Fig. 7; Supplementary Figs. 1 – 4). These parameters

359   show similar patterns with regard to depth, where no significant change with depth is

360   observed   except   more   scattered   distribution   in   the   top   ~25   meters   below   the

361   unconformity (Fig. 7), and no significant change is observed in individual drill cores,

362   especially if the top 10 meters below the unconformity are excluded (Fig. 8). The samples

363   from the hanging wall or footwall, and those in drill core WR-412 far away from the WS

364   Shear Zone, exhibit the same trend as those in the WS Shear Zone (Figs. 7 and 8).

365   Using the graphite thermometer of Beyssac et al. (2002) (T (^{o}C) = -445 R2 + 641),

366   where R2= D1 / (G+D1+D2), the formation temperatures of Gr1 graphite were calculated

367   to be from 516 to 613 ^{o}C (Table 1). There is no discernable trend of temperatures with

368   depth, except an abrupt drop in calculated temperatures in the top ~25 meters below the

369   unconformity (Fig. 9a). For individual drill cores, there is no systematic change in

370   temperatures with depth, especially if the top 10 m below the unconformity is excluded

371   (Fig. 9b-f).

372

373   **Discussion**

374   There is no dispute that graphite-rich fault zones play an important role in the

375   formation of most URU deposits, but the role of graphite during uranium mineralization

376   is still unclear. Roles of graphite can be divided into two categories: chemical and

377   mechanical. In the first category, graphite or hydrocarbons derived from graphite served

378   as the reducing agents to reduce U^{6+} to U^{4+} and precipitate uraninite (Hoeve and Sibbald

379   1978; Hoeve and Quirt 1984; Landais et al. 1993; Alexandre et al. 2005; Dargent et al.

380   2015; Pascal et al. 2016a, b; Martz et al. 2017, 2019; Branquet et al. 2019). In the second

381   category, graphite played the role of a lubricant that facilitated fault reactivation and thus

382   controlled channeling of ore-forming fluids (Kyser et al. 1989; Yeo and Potter 2010).

383   The chemical roles of graphite can be further divided into three scenarios: 1)

384   graphite was directly used as a reducing agent to precipitate uraninite (Alexandre et al.

385   2005); 2) hydrocarbons (especially CH_4) derived from interactions between graphite and

386   aqueous fluids, which took place at or near the site of, and coeval with, uranium

387   mineralization, served as reducing agents to precipitate uraninite (Hoeve and Sibbald

388   1978; Hoeve and Quirt 1984; Landais et al. 1993; Pascal et al. 2016a,b); and 3) CH_4

389   produced from graphite – aqueous fluid reactions at depth prior to uranium mineralization

390   was delivered to the site of mineralization and served as a reducing agent to precipitate

391   uraninite (Dargent et al. 2015; Martz et al. 2017, 2019; Branquet et al. 2019). These three

392   scenarios are discussed below in light of the results obtained in this study. Note, although

393   these scenarios emphasize the chemical roles of graphite, they are not necessarily against

394   the notion that graphite also played a mechanical role in facilitating faulting.

395   As discussed in Yeo and Potter (2010), the hypothesis that graphite was directly

396   used as a reducing agent in uranium mineralization is generally not supported by

397   microscopic observations, i.e., uraninite was not intimately associated with graphite at a

398   micro-scale. This is also the case for the Phoenix uranium deposit. First of all, like other

399   sandstone-hosted (or egress style) URU deposits, the orebodies in the Phoenix deposit

400   overlie, rather than replace, graphite-rich basement rocks (Fig. 2a), thus excluding the

401   possibility of graphite being used directly as a reducing agent at a deposit scale. Secondly,

402   like in other URU deposits, no crystal-scale replacement of graphite by uraninite was

403   observed even when graphitic metapelite was locally mineralized (Fig. 3h). Therefore,

404   textural observations presented in this study do not support the hypothesis that graphite

405   served as a reducing agent for URU mineralization.

406   Additionally, the results from this study do not support the breakdown of graphite

407   at the site of mineralization, because the decrease of graphite abundance towards the

408   unconformity is unclear and unrelated to uranium mineralization. There is no clear trend

409   of decreasing graphite content toward the orebodies except perhaps the top 10 m below

410   the unconformity (Fig. 6). The decrease of graphite content near the sites of mineralization

411   have been reported in many URU deposits, which has been used as an argument that in-situ

412   graphite consumption is related to uranium mineralization (Hoeve and Sibbald 1978;

413   Hoeve and Quirt 1984; Landais et al. 1993). However, the possibility that the graphite

414   consumption was caused by weathering during formation of the unconformity, i.e., before

415   the formation of the Athabasca Basin and uranium mineralization (Pascal et al. 2016a, b),

416   cannot discounted. Furthermore, the uppermost part of the basement have been overprinted

417   by diagenetic fluids of the Athabasca Basin (Adlakha et al. 2014), which may have also

418   contributed to consumption of the graphite. This scenario of paleo-weathering +/-

419   diagenetic overprint is supported by the observation that samples from the hanging wall

420   and footwall of the mineralized WS Shear Zone as well as at a locality ~500 m away from

421   the WS Shear Zone also show a decrease of graphite content near the unconformity (Fig. 6).

422   The dissolution features of graphite (Gr1), including corroded grains (Fig. 3b) and

423   micro-pits (Fig. 3d), may have been produced during the paleo-weathering and diagenetic

424   processes. The slight increase of the degree of structural disorder of graphite near the

425   unconformity, as indicated by Raman spectra parameters (Figs. 7 and 8) and calculated

426   temperatures (Fig. 9), can also be explained by paleo-weathering and diagenetic processes.

427   Although minor contribution of hydrocarbons derived from in situ graphite –

428   aqueous solution reaction to uranium mineralization depicted in the conventional

429   diagenetic-hydrothermal model (Hoeve and Sibbald 1978; Hoeve and Quirt 1984;

430   Landais et al. 1993) cannot be entirely excluded, the reducing agents for uranium

431   mineralization at Phoenix were possibly derived from external sources. The overall

432   reducing environment in the basement is favorable for development of various reducing

433   species in the basement fluids, including CH_4, H_2, Fe^{2+}, CO, and H_2S (Dargent et al. 2015).

434   For sandstone-hosted URU deposits including the Phoenix deposit, Fe^{2+} cannot be an

435   important reducing agent for uranium mineralization, because the alteration halo

436   associated with mineralization is characterized by bleaching (dissolution of hematite in

437   the sandstone) rather than reddening (precipitation of hematite). The more likely reducing

438   agents involved in the URU mineralization are CH_4, H_2, and C_2H_6 as detected in fluid

439   inclusions associated with URU deposits (Dargent et al. 2015; Richard 2017). Although

440   these reducing agents may be pervasive in the basement, they are more likely to develop

441   and accumulate in graphite-rich zones, forming a gas reservoir without a physical

442   boundary (Fig. 10). Such a reservoir may be sustained by the overall low permeability of

443   the surrounding rocks and continuous generation of gases through chemical reactions such

444   as: $2C + 2H_2O = CH_4 + CO_2$; $C + 2H_2O = CO_2 + 2H_2$; and $CO_2 + 4H_2 = CH_4 + 2H_2O$

445   (Dargent et al. 2015).

446   It is well understood that methane can be generated from cracking of larger

447   hydrocarbons at elevated temperatures and pressures through thermogenic processes

448   (Vanderbroucke and Largeau 2007). Significant amounts of methane may be formed

449   during the prograde metamorphism (1840 – 1805 Ma) (Martz et al. 2017) and formation of

450   the flaky graphite (Gr1). The maximum temperature at this time was estimated to be ~ 610

451   ^{o}C (Table 1), which is similar to that estimated by Martz et al. (2017) for metamorphic

452   graphite at the Cigar Lake uranium deposit (~ 640 ^oC) but lower than the peak

453   metamorphism condition of the Trans-Hudson orogeny (~ 800 ^oC, Martz et al. 2017; ~

454   875 ^oC, Adlakha and Hattori 2021). The formation of Gr2, and probably Gr3, likely took

455   place at higher temperatures, as reflected by the almost perfect Raman G band without any

456   D bands in Gr2 (Fig. 4d). A similar occurrence of graphite (as inclusions in quartz and

457   tourmaline) has been reported in the basement rocks of the McArthur River deposit

458   (Adlakha et al. 2000), and the age of the rutile associated with the graphite has been

459   constrained to 1723 +/-12 ~ 1750 +/-5 Ma, which is linked with a thermal event related to

460   asthenospheric upwelling (Adlakha and Hattori 2021). Large amounts of methane may

461   have been produced during this period of time, as testified by the occurrence of CH_4

462   inclusions with Gr2 (Fig. 5). However, the very low density of the methane inclusions, as

463   suggested by the homogenization into the vapor phase (Fig. 5d), the low homogenization

464   temperatures of the associated aqueous inclusions (106 to 276 °C), and the low pressures

465   calculated from these inclusions (3 to 140 bars), all suggest entrapment of these inclusions

466   at shallow depths. The coexistence of methane and aqueous inclusions within individual

467   FIAs (Fig. 5c) suggests fluid immiscibility, and therefore the homogenization temperatures

468   of the aqueous inclusions may represent the tapping temperatures, and the calculated fluid

469   pressures at these temperatures represent the trapping pressure. Even if the trapping

470   temperatures were higher than the homogenization temperatures of the aqueous inclusions,

471   the calculated fluid pressures would still be low due to the low density of the CH_4

472   inclusions. Similar P-T conditions have also been obtained from CH_4 inclusions in other

473 URU deposits (Pascal et al. 2016b). A possible explanation for the apparent contradiction

474 between the high temperature suggested by Gr2 and the low temperature and pressure

475 suggested by the associated fluid inclusions is that the microfractures that host Gr2 and

476 fluid inclusions were reopened during the exhumation process. This hypothesis is

477 supported by variation of homogenization temperatures of CH_4 and aqueous inclusions

478 within the same FIAs. Low salinities of the aqueous inclusions (1.8 to 4.3 wt.% NaCl

479 equivalent), which are in contrast to the basinal brines from the Athabasca Basin (Chu

480 and Chi 2016; Richard et al. 2016), suggests that this reopening did not happen during or

481 after development of brines in the basin, perhaps during the exhumation process of the

482 basement rocks before the formation of the Athabasca Basin.

483 For the reducing gases generated at depth in the basement to participate in the

484 formation of URU deposits, they need to be delivered to the site of mineralization near the

485 unconformity, and the reactivated basement faults likely played a critical role. The WS

486 Shear Zone in the Phoenix deposit, like most of the basement faults that host URU deposits,

487 displays features indicating reverse faulting after the formation of the Athabasca Basin

488 (Kerr 2010; Roscoe 2014; Wang et al. 2018). Such reverse reactivation of the basement

489 faults has been shown to be able to drive egress fluid flow from the basement toward the

490 unconformity (Li et al. 2017, 2018). During episodic reactivation of the basement faults,

491 reducing gases may have been released from the reservoir at depth. In addition to providing

492 the driving force for fluid flow during faulting (seismicity), the tectonic process also

493 enhances the permeabilities of the fault zones, which in turn enhances fluid convection

494   during the interseismic periods (Branquet et al. 2019; Li et al. 2020). Thus, formation of

495   URU deposits may be related to alternating deformation-driven flow and fluid convection

496   due to episodic seismicity (Fig. 10).

497   The environment in which the seismicity, as well as the fluid flow and mineralization

498   events, took place is still controversial. Many authors consider that URU mineralization

499   took place at depths of 5 – 6 km, and fluid pressure fluctuated between lithostatic and

500   hydrostatic regimes (e.g., Pagel 1975; Richard et al. 2016; Martz et al. 2017, 2019;

501   Branquet et al. 2019), whereas others suggest that the mineralization likely took place at

502   depths of ~3 km, and fluid pressure fluctuated between hydrostatic and sub-hydrostatic

503   regimes (Chi et al. 2018b; Wang et al. 2018). We favor the latter model based on the

504   inference of hydrostatic pressure regime in the Athabasca Basin due to dominance of

505   sandstones (Chi et al. 2013), geochrono-stratigraphic constraints (Chi et al. 2018b), and

506   sub-hydrostatic fluid pressures indicated by fluid inclusions (Rabiei et al. 2017, 2021;

507   Wang et al. 2018). According to the first model, the reactivation of the basement faults

508   may be compared to the fault-valve model of Sibson et al. (1988), whereas the second is

509   similar to the seismic suction pump model of Sibson (1987, 2001). We propose here that

510   the seismicity was triggered at the base of the basement faults, which was ~ 5 km below the

511   unconformity, where the deformation regime was transitional between brittle and ductile,

512   and fluid pressure was normally lithostatic and dropped to hydrostatic during fracturing, as

513   depicted by the fault-valve model (Sibson et al. 1988). At the upper tip of the fault near the

514   unconformity surface, where URU mineralization took place, the fluid pressure was

515 normally hydrostatic and dropped to sub-hydrostatic during seismic fracturing, causing

516 instant fluid boiling and drainage of basement-derived fluids rich in reducing gases. The

517 upward flow of basement fluids and gases would continue after these seismic events,

518 providing reducing agents for uranium mineralization in the inter-seismic periods (Fig.

519 10).

520 Based on the above discussions, the nature of the association of URU mineralization

521 and reactivated graphite-rich basement faults may be envisaged as dual roles of graphite:

522 on one hand, graphite provided the most important ingredient for making reducing gases

523 (especially CH_4 and H_2) at depth, and on the other hand, the reactivation of the basement

524 faults, enhanced by graphite as a lubricant, helped deliver reducing gases to the site of

525 mineralization. The model proposed here is different from the conventional

526 diagenetic-hydrothermal model (Hoeve and Sibbald 1978; Hoeve and Quirt 1984) in that

527 the generation of hydrocarbons required for uranium mineralization did not take place at or

528 near the site of mineralization, but rather at depth (> 5 km below the unconformity). In

529 addition, hydrocarbons were not produced at the time of mineralization, but were generated

530 mainly during metamorphism and subsequent fluid-rock reactions and then stored in and

531 around the source rocks. Our model is also different from those that assumed great burial

532 depths of the unconformity during mineralization (5 – 6 km; Richard et al. 2016; Martz et

533 al. 2017, 2019; Branquet et al. 2019), even though both suggest that the reducing gases

534 were derived from depths instead of in situ. Our combined fault-valve and suction pump

535 model (Fig. 10), with the reactivated basement faults connecting the sites of mineralization

536   with the reservoir of reducing gases, is a plausible explanation of the genetic link between

537   URU deposits and graphitic basement faults.

538

539   **Implications**

540   This study uses Raman spectroscopy to examine the temporal and spatial variation of

541   graphite along a reactivated basement fault controlling the Phoenix URU deposit in the

542   Athabasca Basin. The purpose was to evaluate the role of graphite in URU mineralization,

543   which has been investigated for over four decades and remains debated. The results

544   indicate that although URU mineralization is spatially associated with underlying

545   graphitic lithologies in the basement, the graphite in the immediate host rocks did not play

546   a major role in uranium mineralization, either directly as a reducing agent, or as precursor

547   of hydrocarbons. Instead, hydrocarbons generated from graphite – fluid reactions at depth

548   were likely the source of reducing agents for the uranium mineralization. These reducing

549   gases were tapped during fault reactivation, which was facilitated by graphite as a lubricant,

550   and delivered from the reservoir at depth to the site of mineralization.

551   Raman spectroscopy has been previously applied to the study of graphite associated with

552   URU deposits, but the great number of measurements from spatially spread out samples in

553   this study provides new insights on the role of graphite. This case study serves as an

554   example of how a proven technology can tackle some long-standing scientific problems

555   using a different approach. The model and method developed in this study are applicable to

556   other studies investigating the hydrodynamic link between shallow, hydrostatic-dominated

557   and deep-seated, lithostatic-dominated environments. The conditions and geological

558   processes (both mechanical and chemical) in such transitional environments are of broad

559   interest to geoscientists working in the general fields of tectonics, mineral systems and

560   seismology.

803

804 **Captions of Figures**

805   Figure 1. Maps and cross section showing the locations of samples from the Phoenix

806   uranium deposit used in this study. a) Location of the Athabasca Basin in Canada and

807   the location of the Phoenix deposit in the Athabasca Basin (modified from Card et al.

808   2007); b) Basement geology of the Phoenix deposit (modified from Roscoe 2014); the

809   insert shows the locations (collar) of diamond drill holes examined in this study; c)

810   Schematic cross section of the Phoenix deposit and neighboring areas (modified from

811   Arseneau and Revering 2010). Note the mineralized zone lies above the graphitic

812   metapelite unit in the basement; it is mainly hosted in the sandstone above the

813   unconformity, but its lower part extends into the basement. Sandstone units: Rd =

814   Read Formation, MF = Manitou Falls Formations: MFb = Bird Member, MFc =

815   Collins Member, MFd = Dunlop Member. Note the mineralized zone lies above the

816   graphitic metapelite unit in the basement; it is mainly hosted in the sandstone above

817   the unconformity, but its lower part extends into the basement. Modified from Wang et

818   al. (2018).

819   Fig. 2. Photographs of drill cores showing: a) massive uraninite overlying graphitic

820   metapelite in the basement; the orebody is surrounded by altered sandstone above and

821   altered basement rocks below, and the lower boundary of the orebody coincide with the

822   unconformity surface; b) graphitic metapelite with pervasive graphite (Gr1) crosscut by

823   graphite in a fracture (Gr3?); c) graphic metapelite with dispersed graphite (Gr1)

824   crosscut by a quartz vein which is cut by relatively coarse graphite (Gr3); d) graphite

825   (Gr3) occurring in fractures that crosscut pegmatite.

826   Fig. 3. Photomicrographs showing occurrences of different generations of graphite and

827   their features. a) flaky graphite (Gr1) in graphitic metapelite far from the unconformity;

828   b) graphite in metapelite (Gr1) showing equant shape and dissolution features in a

829   sample close to the unconformity; c) flaky graphite (Gr1) showing variable reflectance;

830   d) micro-pits in flaky graphite (Gr1) in metapelite; e) blebs of graphite (Gr2) occurring

831   as inclusions in replacement quartz in a metapelite; the insert is a bleb of Gr2 showing

832   homogeneous reflectance; f) graphite occurring in fractures (Gr3) associated with pyrite;

833   g) amorphous carbonaceous matter (Gr4) occurring in growth zones in drusy quartz; h)

834   a mineralized graphitic metapelite from the Gryphon Zone showing that graphite (Gr1)

835   and uraninite occur close to each other (< 1 mm) but generally not in contact (except

836   minor touch at the lower left corner and middle right). Note a, b and e are in transmitted

837   light, and the rest are in reflected light.

838   Fig. 4. Raman spectra of different generations of graphite (in the first order region). a) Gr1

839   showing only the G band or G band with D1 and D2 bands; b) comparison between Gr1

840   graphite with micro-pits and Gr1 without micro-pits; c) comparison between a hollow

841   point and area near the hollow point in Gr1; d) Gr2 showing only the G band without

842   discernable D bands; e) Gr3 showing only the prominent G band with or without a

843   minor D1 band; f) Gr4 showing a broad G band and a significant D1 band.

844   Fig. 5. a) occurrences of rounded graphite (Gr2) with or without a visible fluid phase,

845   which shows Raman peaks of CO_2, CH_4, and N_2; note the bump at the base of the CH_4

846   peak may be related to unrecognized hydrocarbons, whereas the shoulder to the right of

847   the bump could be caused by epoxy; b) a rounded graphite (Gr2) without a visible fluid

848   phase showing Raman peaks of CH_4 and N_2; note the sharp peak at 2918 may look like

849   a cosmic ray effect, but its occurrence in other Gr2 grains suggests that it is not related to

850   cosmic ray; c) occurrence of CH_4 and aqueous inclusions with rounded graphite (Gr2) in

851   the same fluid inclusion assemblage (FIA) in a healed fracture; d) a CH_4 inclusion that

852   shows only one phase (vapor) at room temperature and two phases (liquid and vapor) at

853      $-185^{o}C$.

854   Fig. 6. Diagrams showing graphite contents (vol.%) versus distance from the unconformity.

855   No significant trend is discernable, especially if the top 10 m is excluded. See text for

856   discussion.

857   Fig. 7. Diagrams showing various Raman spectra parameters (D1/G, D/G, RA1 and R2, all

858   as area ratios) indicating degree of structural disorder of graphite versus distance from

859   the unconformity. No significant trend is discernable except for more scattered

860   distribution toward the unconformity surface. See text for discussion.

861   Fig. 8. Diagrams showing D1/G area ratios of Raman spectra of graphite indicating degree

862   of disorder versus distance from the unconformity. No significant trend is discernable.

863   See text for discussion.

864   Fig. 9. Diagrams showing temperatures calculated from graphite thermometer (Beyssac et

865   al. 2002) versus distance from the unconformity. No significant trend is discernable

866   except for a few relatively low temperatures in the top ~25 m to the unconformity. See

867   text for discussion.

868   Fig. 10. A schematic model illustrating the genetic relationship between a graphic

869   basement fault and URU mineralization. Basement fluids enriched in reducing gases are

870   stored at depth (below ~5 km from the unconformity or ~8 km from the surface). During

871   seismic activity, the basement fluids were tapped by the reactivated fault and delivered

872   to the upper part of the fault near the unconformity. Fluid flow was controlled by the

873   'fault-valve' mechanism at the base of the fault, where fluid pressure fluctuates between

874   lithostatic and hydrostatic values, and by the 'suction pump' mechanism at the top of the

875   fault, where fluid pressure fluctuates between hydrostatic and sub-hydrostatic (Sibson

876   1987, 2001; Sibson et al. 1988). During inter-seismic periods, the enhanced

877   permeability of the fault zones allows continuous drainage of the basement fluids for a

878   certain period of time (Li et al. 2020). Uranium mineralization resulted from mixing of

879   oxidizing, U^{6+}-rich basinal brines with reducing basement fluids near the unconformity.

880   These seismic - interseismic processes were repeated multiples to form a uranium

881   deposit.

882

* Most samples are from the graphitic metapelite – SW Shear Zone except those in the shaded rows, which are from the hanging wall and footwall of the SW Shear Zone (those from drill core WR-412 are ~500 m to the west of the SW Shear Zone)

** RA1=(D1+D4)∕(D1+D2+D3+D4+G) area ratio according to Lahfid et al. (2010); R2=D1∕(G+D1+D2) area ratio according to Beyssac et al. (2002)
*** T (°C) = -445 R2 + 641 according to Beyssac et al. (2002)
