16 **ABSTRACT**

17 A hydrothermal quartz vein with REE-U-Au mineralization in the Zimná Voda (Gemeric

18 Unit, Western Carpathians, Slovakia) is associated with contact metamorphism between Permian

19 granites and host phyllites and metaquartzites. It contains unique REE minerals from the

20 monazite and xenotime groups. Monazite-(Ce), monazite-(Nd), monazite-(Sm), and Gd-dominant

21 monazite ["monazite-(Gd)"], along with xenotime-(Y) to Gd-dominant xenotime ["xenotime-

22 (Gd)"] and Gd-rich hingganite-(Y) show heterogeneous compositions and reflect a strong

23 fractionation trend toward the enrichment of MREE (Sm to Dy), particularly Gd. Here, the

24 gadolinium abundance reported in "monazite-(Gd)" ($\leq$23.4 wt% Gd_2O_3) and Gd-rich xenotime-

25   (Y) to "xenotime-(Gd)" ($\leq$28.7 wt% Gd_2O_3) and accompanied by Gd-rich hingganite-(Y) ($\leq$15.8

26   wt% Gd_2O_3), is among the highest Gd concentrations ever reported in natural minerals. The Gd-

27   richest compositions show the following formulae:

28    $(Gd_{0.31}Sm_{0.24}Nd_{0.15}Ce_{0.10}La_{0.05}Dy_{0.03}Y_{0.03}...)_{0.98}PO_4$ ["monazite-(Gd)"],

29    $(Gd_{0.36}Y_{0.32}Dy_{0.13}Sm_{0.08}Tb_{0.05}...)_{0.98}(P_{0.96}As_{0.04})_{1.00}O_4$ ["xenotime-(Gd)"] and

30    $(Y_{0.71}Gd_{0.43}Dy_{0.23}Sm_{0.22}Tb_{0.06}Er_{0.04}Nd_{0.06}...Ca_{0.06})_{1.96}(\square_{0.87}Fe^{2+}_{0.13})_{1.00}(Be_{1.82}B_{0.18})_{2.00}(Si_{1.90}As_{0.10})_{2.}$

31    $_{00}O_8(OH_{1.70}O_{0.30})_{2.00}$ [hingganite-(Y)]. The MREE-rich monazites, xenotimes, and hingganite-(Y)

32   precipitated in response to the alteration of primary uraninite, brannerite, and fluorapatite by low-

33   temperature hydrothermal fluids of heterogeneous compositions on a micro-scale. These are

34   responsible for the strong enrichment of individual MREE, especially Gd in the secondary

35   minerals. This is accompanied by the advancing development of the W-type tetrad effect on REE

36   through monazite species. The substantial incorporation of Gd into both REE-selective monazite

37   and xenotime structures that are accompanied by LREE vs. HREE segregation indicates the

38   possibility of differently-sized REE^{3+} miscibility in $REEPO_4$ solid solutions, as well as the

39   stabilization of the Gd-rich orthophosphate structure by substitution of the remaining *A*-site

40   cations with smaller HREE+Y in the xenotime-type, and/ or larger LREE in the monazite-type

41   structure.

46   **INTRODUCTION**

47   Accessory monazite-group minerals (MGM) and xenotime-group minerals (XGM) are

48   widespread in numerous lithologies, including various magmatic, metamorphic, and sedimentary

49   rocks, as well as hydrothermal, authigene, and supergene systems. Monazite contains dominant

50   trivalent LREE (light Ln: La–Sm) based on their preference of monazite-type crystal structure

51   (Ni et al. 1995). Among them, monazite-(Ce) is the most common end-member, whereas

52   monazite-(La), monazite-(Nd), and monazite-(Sm) occur as rare minerals only in specific

53   pegmatite, post-magmatic or sedimentary environments (e.g., Graeser and Schwander 1987;

54   Demartin et al. 1991b; Pekov 2000; Massau et al. 2002; Dowman et al. 2017). There are only two

55   known end-members in the XGM. Xenotime-(Y) is by far the most widespread and contains the

56   dominant Y^{3+}, as well as usually low contents of other HREE (heavy Ln, Tb–Lu) and negligible

57   amounts of LREE. On the other hand, xenotime-(Yb) and Yb-, Dy-, and Gd-rich xenotime-(Y)

58   belong to very rare minerals occurring in some granitic pegmatites and metamorphic-

59   hydrothermal lithologies (Demartin et al. 1991a; Förster and Rhede 1995; Förster 1998b; Buck et

60   al. 1999; Massau et al. 2000; Repina 2011, 2014; Franz et al. 2015). Despite having a generally

61   coherent behavior, selective REE mobilization and fractionation in aqueous systems is quite

62   common and has been reported previously from different geochemical environments (e.g.,

63   Seredin 1996; Morgan et al. 2012; Lee et al. 2013; Franz et al. 2015; Migdisov et al. 2019;

64   Ondrejka et al. 2018; Abedini et al. 2019; Anenburg et al. 2020b).

65   Here, we describe a unique case of substantial middle REE (MREE, Sm–Dy) enrichment and

66   localized Gd-predominance in monazite, xenotime, and Gd-rich hingganite-(Y), which is due to

67   the low-temperature alteration of primary uraninite, brannerite and fluorapatite, as well as the

68   subsequent remobilization and precipitation of REE by aqueous media from the hydrothermal

69   REE-U-Au quartz vein in Zimná Voda near Prakovce, eastern Slovakia. This study presents the

70   first description of exceptionally Gd-rich monazite to Gd-dominant "monazite-(Gd)", as well as

71   Gd-, Dy-rich xenotime-(Y) to "xenotime-(Gd)" and Gd-rich hingganite-(Y) based on detailed

72   EPMA study; all phases belong to the highest published Gd contents in natural minerals.

73   Moreover, "monazite-(Gd)" and "xenotime-(Gd)" are potential new minerals. A detailed

74   structural study, which is necessary for its approval by the IMA-CNMNC, will be the subject of

75   our future investigation. To date, lepersonnite-(Gd), which is a rare REE-uranyl carbonate from

76   the Shinkolobwe U deposit in the DR Congo (Deliens and Piret 1982), represents the only

77   approved Gd-dominant mineral found in nature.

78

79   REGIONAL GEOLOGY

80   The investigated Zimná Voda occurrence is located in the Lower Paleozoic metamorphic

81   rocks of the Bystrý Potok Formation, a part of the Gelnica Group in the Gemeric tectonic Unit of

82   the Western Carpathians, which is part of the Alpine-Carpathian Mountain belt (Fig. 1a). The

83   Gelnica Group is represented by a several-thousand metre thick Paleozoic flysch sequence with

84   important rhyolite-dacite admixture (Ivanička et al. 1989). These rocks have undergone regional

85   metamorphism under lower greenschist-facies conditions (Faryad 1991). The Bystrý Potok Fm.

86   (Ordovician to Silurian) is formed mainly by black cherts, quartz-sericite or graphitic phyllites,

87   greywackes, metarhyolites and tuffites, rarely by actinolite shales (Bajaník et al. 1983; Ivanička

88   et al. 1989), Fig. 1b. The metavolcanic rocks yielded Middle Ordovician U–Pb SHRIMP zircon

89   ages (~460–465 Ma; Vozárová et al. 2010). These metamorphic rocks are intruded by Permian

90   Gemeric granites (~260–270 Ma; e.g., Villaseñor et al. 2021).

91   The Zimná Voda REE-U-Au vein mineralization is located near the main ridge of the

92   Slovenské Rudohorie Mts. approximately 5.6 km to the S of the village of Prakovce and 600 m to

93   the NW of the elevation point Tri Studne and an altitude of ~950 m. The geographical

94   coordinates of the occurrence are 48.767°N and 20.913°E.

95   Two quartz veins (Western and Eastern) containing U and Au mineralization were found in

96   the area. The subject of our research focused on the more significant Western vein. The vein is

97   located in sericitic phyllites, with interbeds of fine-grained metaquartzites. These metamorphic

98   rocks are intruded by Permian granites in the Hummel site, ~600 m to the SW of the Zimná Voda

99   occurrence. The Western vein conforms to the metamorphic schistosity of the surrounding rocks.

100   It has an E–W direction, as well as a total length of ~90 m with an average inclination of 65° to

101   the S. The thickness of the vein ranges from 3 to 30 cm. The vein is slightly corrugated and

102   segmented by transverse faults into segments of 3 to 55 m long, while termination of the vein on

103   both tails is also tectonic. Drilling surveys showed a tectonic zone cutting the vein at a depth of

104   7–10 m. The main vein body is accompanied by short veinlets with U-Au mineralization, and

105   quartz veins without ore mineralization. The host rocks are hydrothermally-altered with

106   disseminated pyrite in a contact zone that is 2 to 8 m wide. Along the contact, the rocks are

107   intensively sericitized and locally silicified. Both the quartz veins with ore mineralization and the

108   host rocks are intensively limonitized.

109   In addition to dominant quartz, the following minerals were identified in the veins (Rojkovič

110   et al. 1997): uraninite, brannerite, rutile, gold, bismuth, bismuthinite, pyrite, arsenopyrite,

111   cobaltite, glaucodot, molybdenite, galena, tetrahedrite-(Fe), fluorapatite, monazite-(Ce),

112   xenotime-(Y), muscovite, chlorite, and tourmaline; supergene minerals are represented by

113   goethite, trögerite(?), zeunerite, and scorodite. The maximum U content detected in the ore was

114   11850 ppm (3076 ppm in average), the Au content ranges ≤3500 ppm, 38 ppm on average

115   (Rojkovič et al. 1997). The mineralization probably originated by fluid-driven hydrothermal

116 mobilization of REE, U, and Au from the surrounding metamorphic rocks by intrusion of the

117 Permian granitic rocks (Rojkovič et al. 1997, 1999).

118

119 **METHODS**

120 The field samples were collected from old exploration trenches using an SGR scintillation

121 radiometer. Hand-specimen sized pieces were sampled and numbered from ZV-1 to ZV-6. The

122 mineral assemblages and textures were identified by electron probe microanalysis (EPMA) and

123 observed using back-scattered electron (BSE) image. The Gd-predominance in minerals was

124 identified only in one sample (ZV-2). In total, 10 polished thin sections of this sample were

125 studied in detail.

126 Chemical composition of the minerals was studied by EPMA in wavelength-dispersive

127 spectrometry (WDS) mode, and X-ray elemental mapping using a JEOL JXA-8530F electron

128 microprobe at the Earth Science Institute, Slovak Academy of Sciences in Banská Bystrica,

129 Slovakia. An accelerating voltage of 15 kV and a probe current of 20 nA were used. The typical

130 spot beam diameter varied from 2 to 8 μm; a more focused ≤1–3 μm beam was used only

131 occasionally to avoid any intermediate composition in strongly heterogeneous micro-scale areas.

132 A series of X-ray elemental maps was acquired with different resolution (0.06–0.23 μm/pixel)

133 and dwell time (30–100 ms). The EPMA was calibrated using natural and synthetic standards

134 (Supplementary Table 1), and raw counts were converted to wt% of oxides using *ZAF* matrix

135 correction. The WDS scan of peak and background positions for selected REE elements analyzed

136 are shown in Supplementary Figure 1. Corrections of line interferences were provided using the

137 method by Åmli and Griffin (1975). The detection limit for all elements is typically between 0.01

138 and 0.02 wt%.

139   Element contents in the mineral formulae are expressed in atoms per formula unit (apfu). The

140   uraninite formula was normalized to 2 oxygen atoms, brannerite to 3 cations, and the partition of

141   total uranium between U^{4+} and U^{6+} in brannerite was calculated from a neutral charge balance.

142   Fluorapatite was calculated based on $\Sigma(M+T) = 8$ cations and $OH+F+Cl = 1$ apfu (Pasero et al.

143   2010). The monazite and xenotime formulae were normalized to 4 oxygen atoms. The gadolinite-

144   supergroup nomenclature (Bačík et al. 2017) is used for hingganite-(Y) formula calculation,

145   normalized on the basis of A = 2 cations (general chemical formula: $A_2MQ_2T_2O_8\varphi_2$). The B_2O_3

146   and BeO contents (wt%) were calculated from the charge balance according to Be = 6 – [20 –

147    $\Sigma PC – OH$] (where PC is the sum of charges for all cations except B and Be) and B = 2 – Be.

148   REE patterns were fitted, and tetrad effect were calculated using BlambdaR/ AlambdaR method

149   (Anenburg 2020; Anenburg and Williams 2022).

RESULTS

</div>

Uraninite

152   Primary hypogene uraninite (uraninite I) UO_2 is an abundant mineral and, together with

153   brannerite, the most important U carrier. It usually forms large botryoidal aggregates (≤1.2 mm in

154   size) and microcrystalline masses with globular microstructures, often showing concentric bands

155   (pitchblende variety) with numerous desiccation cracks filled with quartz, brannerite, or

156   supergene uranyl arsenates-phosphates formed due to the oxidation-hydration alteration of

157   uraninite (Figs. 2a–2d and 3a). The relatively homogeneous chemical composition close to the

158   theoretical UO_2 end-member is a characteristic feature of uraninite I. While the U content varies

159   between 83.0 and 90.6 wt% UO_2 (0.65–0.92 apfu U), the Th concentrations are negligible (≤0.1

160   wt% ThO_2) (Table 1 and Supplementary Table 2). The Y content is relatively low (≤1.0 wt%

161   Y_2O_3, 0.03 apfu Y) and other REE attain 2.9 wt% REE_2O_3 (0.04 apfu REE). The distribution of

162 REE within the botryoidal aggregate suggests their partial removal in altered central parts and

163 rims (Figs. 3b and 3c). The average chondrite-normalized REE pattern of uraninite I shows

164 relative enrichment in MREE and corresponding depletion in LREE and HREE (Fig. 4a).

165 Uraninite I is W-rich (1.6–4.2 wt% WO_3, ≤0.04 apfu W), low concentrations of Mo, As and Fe

166 are usually detected (Table 1 and Supplementary Table 2). In situ U–Th–total Pb EPMA age

167 determination of uraninite I gave a Triassic (Anisian) age of 246±0.6 Ma (n=42, MSWD: 8.0;

168 Ondrejka et al. in prep.).

169 Secondary uraninite II forms alteration rims around uraninite I (Figs. 2a, 2b and 2d), or partly

170 recrystallized, metamict(?) and hydrated domains in the central parts of uraninite I (Figs. 2c and

171 2d). It shows more complex internal microtexture characterized by porosity and fractures.

172 Uraninite II has a strongly heterogeneous composition, low totals and non-ideal stoichiometry

173 with ≤9.3 wt% WO_3, ≤3.2 wt% Sb_2O_5, ≤3.7 wt% FeO, ≤7.0 wt% Y,REE_2O_3, ≤2.7 wt% As_2O_5,

174 but low P and Si contents.

175 The youngest uraninite III is represented by newly-formed tiny crystals (0.5–8 μm in size),

176 which form clusters in the proximity of uraninite I (Figs. 2a, 2d and 2g), or disseminated

177 inclusions within the REE phosphates (Figs. 5a and 5c). It is characterized by an elevated Y

178 content (2.5–5.8 wt% Y_2O_3, ≤0.14 apfu Y) and other REE (1.9–6.6 wt% REE_2O_3, ≤0.1 apfu

179 REE); while the concentration of other trace elements (Si, W, Mo, Sb) are negligible and mostly

180 below the detection limit (Table 1 and Supplementary Table 2).

181

182 **Brannerite**

183 Brannerite, ideally UTi_2O_6, is a common mineral at Zimná Voda and the main U carrier

184 together with uraninite. It usually forms the fillings of cavities, desiccation cracks, and the central

8

185 parts of the uraninite aggregates (Fig. 2a) or large and disseminated crystals, as well as cataclased

186 quartz-brannerite aggregates (≤1 mm in size) in close association with gold and uraninite (Figs.

187 2e and 2f). The chemical composition of primary brannerite I is relatively uniform and varies

188 within 0.2–1.7 wt% REE_2O_3 (≤0.05 apfu REE). Tungsten (≤3.4 wt% WO_3, ≤0.07 apfu W) and Sb

189 (≤1.2 wt% Sb_2O_5, ≤0.03 apfu Sb) are always present; locally slightly elevated Nb content was

190 detected (≤2.0 wt% Nb_2O_5, ≤0.07 apfu Nb).

191   Some crystals of brannerite consist of two generations, where unaltered brannerite I forms the

192 outer zone of the crystals, while altered domains of brannerite II are located in their central parts

193 (Fig. 2f). Brannerite II differs from brannerite I mainly in U and REE concentrations; brannerite

194 II shows lower U (22.7–39.8 wt% UO_2, 0.36–0.62 apfu U), but markedly higher REE (4.4–8.4

195 wt% REE_2O_3, 0.12–0.26 apfu REE), especially Y and Gd (≤4.2 wt% Y_2O_3, 0.16 apfu Y and 2.5

196 wt% Gd_2O_3, 0.06 apfu Gd), as well as higher Sb, Nb, Si, Al, Fe, and Mn contents (Table 1 and

197 Supplementary Table 3). The chondrite-normalized REE pattern shows typical MREE

198 enrichment in a secondary (altered) assemblage (Fig. 4b). The brannerite II analyses reveal low

199 oxide totals (~80–93 wt%) in comparison to brannerite I (94–98 wt%), which likely indicates its

200 hydrated and metamict nature (Table 1 and Supplementary Table 3).

201

202 **Fluorapatite**

203   Primary fluorapatite is an abundant hypogene phosphate mineral and occurs as subhedral or

204 anhedral crystals (≤100 μm in size) that are closely associated with other REE phosphates and Fe

205 arsenates scattered in the quartz-muscovite matrix (Fig. 2g). The chemical composition of

206 fluorapatite is relatively uniform: ≤0.6 wt% REE_2O_3 (≤0.02 apfu REE) and ≤0.2 wt% Y_2O_3

207 (≤0.01 apfu Y) reflecting only negligible input of the britholite and/or belovite components. The

9

208 average of the chondrite-normalized REE pattern shows relative enrichment in MREE and

209 corresponding depletion in LREE and HREE (Fig. 4c). The F/(F+OH) atomic ratio attains 0.93 to

210 1.00 and ≤0.1 wt%. The compositions show very low amounts of other divalent cations (Mn, Sr,

211 Mn; Table 1 and Supplementary Table 4).

212

213 **Monazite-group minerals**

214 The MGM are the main LREE carriers in the Zimná Voda occurrence. They form numerous

215 crystals or crystal aggregates (≤150 μm in size), usually as intergrowths with xenotime-(Y),

216 fluorapatite, and uraninite III (Figs. 5a–5d and 5f). Four members of MGM could be recognized:

217 monazite-(Ce), the most common and the only LREE phosphate in all the samples except for ZV-

218 2, whereas, monazite-(Nd), monazite-(Sm), and "monazite-(Gd)" occur only in the ZV-2 sample

219 (Fig. 5d). The monazite-type structure of these species has been confirmed by micro-Raman

220 spectroscopy (see Supplementary Material). The composition of individual crystals is relatively

221 homogeneous without any distinct variations in the core-rim profile. However, a heterogeneous

222 composition reflecting irregular zones of different REE distribution may occur locally (Fig. 3d-

223 3i).

224 The MGM have the following major REE proportions: monazite-(Ce) has compositions with

225 Ce>Nd>Sm>Gd (16–26 wt% Ce_2O_3, 0.23–0.37 apfu Ce; 3–10 wt% Gd_2O_3, 0.03–0.13 apfu Gd).

226 Monazite-(Nd) shows compositions with Nd>Sm~Ce>Gd (15–25 wt% Nd_2O_3, 0.21–0.35 apfu

227 Nd; 5–13 wt% Gd_2O_3, 0.06–0.16 apfu Gd). Monazite-(Sm) reveals Sm>Gd~Nd>Ce (15–20 wt%

228 Sm_2O_3, 0.20–0.27 apfu Sm; 10–19 wt% Gd_2O_3, 0.13–0.25 apfu Gd). Finally "monazite-(Gd)"

229 displays Gd>Sm>Nd>Ce (17–23 wt% Gd_2O_3, 0.22–0.31 apfu Gd; 15–19 wt% Sm_2O_3, 0.20–0.25

230 apfu Sm) (Table 1 and Supplementary Table 5). In general, the element distribution in MGM

10

231 shows an enrichment trend from La–Nd to Sm–Dy with Sm~Gd>Nd>Ce>La (MREE>LREE)

232 and equally negligible Ho–Lu (HREE)+Y abundances (Fig. 6). Although different REE^{3+} are the

233 dominant cations in the corresponding MGM members, their chondrite-normalized REE patterns

234 exhibit the conspicuous maxima at Sm and Gd. However, the patterns of Nd-, Sm-, and Gd-

235 dominant monazite are partly distinct from monazite-(Ce), which shows a less clear maximum at

236 Sm, but more enriched in La and Ce and conspicuously depleted in HREE (Fig. 4d).

237 Interestingly, there are also distinct differences in the shape of the first tetrad (La-Ce-Pr-Nd)

238 which shows a downward concave W-type curvature, progressively developing from monazite-

239 (Ce) to "monazite-(Gd)" with average t1 = 0.63, (Mnz-Ce) to t1 = 8.64 ("Mnz-Gd") in the ZV-2

240 sample (calculation sensu Minami and Masuda 1997; Fig. 4e).

241 Yttrium is generally low (≤1.0 wt% Y_2O_3; ≤0.02 apfu Y, occasionally ≤4.0 wt% Y_2O_3; ≤0.08

242 apfu Y) and actinides are very low, (≤0.3 wt% ThO_2+UO_2; occasionally ≤3.2 wt%; ≤0.03 apfu

243 Th+U). Some crystals contain slightly elevated As (≤1.3 wt% As_2O_5; ≤0.03 apfu As) and Fe

244 (≤2.2 wt% FeO_{total}; ≤0.07 apfu Fe). Other trace elements (Ca, Si, S, and Sr) have negligible

245 concentrations, or they are below detection limits (Table 1 and Supplementary Table 5).

246

247 **Xenotime-group minerals**

248 In the studied occurrence, the XGM are the main Y+HREE carrier together with rare

249 hingganite-(Y). They form numerous crystals and massive aggregates (≤100 μm in size), usually

250 as intergrowths with MGM and with tiny inclusions of uraninite, or in close association with

251 uranyl arsenates or phosphates (Figs. 5a–5g). Xenotime-(Y) usually forms central parts of

252 crystals (xenotime I), whereas Gd-rich xenotime-(Y) to Gd-dominant "xenotime-(Gd)" (xenotime

253 II) are located in the marginal parts of the aggregates or as veinlets in xenotime I (Figs. 3j-3o and

11

254   Figs. 5a–5d, 5f, 5g). The xenotime-type structure of these species has been confirmed by micro-

255   Raman spectroscopy (see Supplementary Material).

256   In contrast to MGM, the XGM display mostly irregular and convolute zonation in some

257   places, as well as heterogeneous composition reflecting different Y/(Gd+Dy) and locally

258   (U+Th)/REE growth zone ratios. This observed core-rim chemical heterogeneity of individual

259   XGM crystals contrasts markedly with MGM. The distribution of Y, Gd, and Dy generally

260   clusters XGM into the following groups: xenotime I is characterized by high Y content (35–46

261   wt% Y_2O_3, 0.64–0.81 apfu Y) and relatively low content of Gd and Dy (≤8.5 wt% Gd_2O_3, ≤0.1

262   apfu Gd and ≤8.4 wt% Dy_2O_3, ≤0.09 apfu Dy, respectively); whereas xenotime II contains low Y

263   (18–33 wt% Y_2O_3, 0.37–0.61 apfu Y) and elevated Gd, Dy and Tb (11.5–28.7 wt% Gd_2O_3, 0.13–

264   0.36 apfu Gd; 7.9–14.4 wt% Dy_2O_3, 0.09–0.17 apfu Dy and 4.0 wt% Tb_2O_3, 0.05 apfu Tb) (Table

265   1 and Supplementary Table 6; Fig. 6). The compositions with slight atomic dominance of Gd

266   over Y (0.34–0.36 apfu Gd vs. 0.31–0.34 apfu Y), which corresponds to "xenotime-(Gd)" were

267   detected in four analyses (Fig. 7).

268   The chondrite-normalized REE pattern of xenotime I shows a different REE distribution

269   compared to xenotime II (Fig. 4f). It has the most extensive M-type tetrad effect on t3 and t4

270   tetrads with average t3 = -4.74 and t4 = -8.44 (Fig. 4g). The Gd-rich xenotime II has a significant

271   upward convex MREE pattern with a maximum in Gd and a less distinct M-type tetrad effect

272   signature compared to xenotime I (Fig. 4f). Uranium has an average value 0.5 wt% UO_2 in

273   xenotime I and 0.7 wt% UO_2 in xenotime II. Thorium concentration in xenotime I+II is below the

274   detection limits. Some crystals of xenotime II contain slightly elevated As (≤2.3 wt% As_2O_5) and

275   Fe (≤2.5 wt% FeO_{total}) (Table 1 and Supplementary Table 6).

276

Hingganite-(Y)

Hingganite-(Y), ideally [$Y_2 \square Be_2 Si_2 O_8 (OH)_2$] is a rare mineral and sporadically present in the quartz-muscovite gangue. It usually forms large solitary crystals (≤300 μm in size). It has mostly irregular zonation and strongly heterogeneous composition in BSE, reflecting different Y/(Gd+Sm) growth zone ratio (Figs. 3p, 3r and Fig. 5h). The dark domains (hingganite I) are strongly Y-dominant in composition (26.2–30.9 wt% Y_2O_3, 1.2–1.4 apfu Y). Other major REE cations at A-site are Dy (8.8–10.4 wt% Dy_2O_3; ≤0.3 apfu Dy) and Gd (3.7–7.4 wt% Gd_2O_3, ≤0.2 apfu Gd). The bright domains (hingganite II; Fig. 5h) are richer in MREE, particularly in Gd (≤15.8 wt% Gd_2O_3, ≤0.4 apfu Gd) and Sm (≤9.7 wt% Sm_2O_3, ≤0.3 apfu Sm; Table 1 and Supplementary Table 7, Fig. 6). The chondrite-normalized REE patterns of both hingganites show a very similar convex shape with the hump on MREE and with the maximum in Gd and Tb respectively (Fig. 3h). Additionally, Y+REE, Ca is the other cation present at the A-site in low amounts (0.5–0.8 wt% CaO, ≤0.08 apfu Ca) (Fig. 8). Hingganite I+II shows a characteristic dominant M-site vacancy (0.51–0.63 pfu); however, two analyses show dominant Fe^{2+} at M-site (vac. 0.48–0.49 pfu) and correspond to gadolinite-(Y). In general, the M-site is partly occupied by Fe (5.8–7.7 wt% FeO, ≤0.52 apfu Fe), since all other possible cations are below 0.01 apfu (Table 1 and Supplementary Table 7).

DISCUSSION

Gd and MREE abundances in natural minerals

Gadolinium-dominant and Gd-rich minerals are generally quite rare in nature due to the low, absolute abundance of Gd, which is relative to other, more abundant REE (especially Ce, Nd, La, Y) in the Earth's upper crust (e.g., Hazen et al. 2015). This includes the relatively strong,

13

300   coherent lanthanides partitioning, which is dependent mainly on charge and ionic radius-

301   controlled behavior (CHARAC) (Bau 1996; Rezaei Azizi et al. 2017). Selective enrichment of

302   Gd or other individual MREE and HREE in terms of absolute abundances is a rare process and

303   does not appear to be related to specific lithologies and environments (cf. Demartin et al. 1993;

304   Massau et al. 2000; Čopjaková et al. 2011; Hannigan and Sholkowitz 2001; Grawunder et al.

305   2014; Franz et al. 2015).

306   The only IMA-CNMNC approved, naturally-occurring Gd-dominant mineral is lepersonnite-

307   (Gd), $CaGd_2(UO_2)_{24}(CO_3)_8Si_4O_{28} \cdot 60H_2O$ (Deliens and Piret 1982), which, however, contains a

308   relatively low absolute concentration of essential Gd (2.1 wt% Gd_2O_3) together with minor Dy,

309   Y, and Tb. On the other hand, the extent of enrichment of Gd (La, Nd, and Sm) in MGM and Gd

310   (Yb and Dy) in XGM is usually ≥10 wt% REE_2O_3. The highest Gd_2O_3 content in MGM

311   described to date is most likely 13.5 wt% (accompanied by 14.3 wt% Sm_2O_3) in monazite-(Sm)

312   from its type locality of Annie Claim, Manitoba, Canada, where it occurs in a lepidolite-subtype

313   granitic pegmatite (Massau et al. 2002). The highest Gd_2O_3 content in xenotime-(Y) noted to date

314   is 25 wt% from the quartz vein of Au-REE mineralization in the Nether-Polar Urals, Russia

315   (Repina 2010, 2011) and 12.6 wt% in gadolinite-(Y) from Alpine fissures in Glogstafelberg, Val

316   Formazza, Italy (Demartin et al. 1993).

317   Our reported Gd abundances in MGM (≤23.4 wt% Gd_2O_3) and XGM (≤28.7 wt% Gd_2O_3),

318   accompanied by Gd-rich hingganite-(Y) (≤15.8 wt% Gd_2O_3) from the Zimná Voda REE-U-Au

319   quartz vein mineralization represent the highest Gd concentrations in these minerals worldwide,

320   and are documented by appropriate methods and corresponding analytical data. We emphasize

321   the use of appropriate and precise analytical methods, since there are published data that

322   document the possible presence of other Gd-dominant minerals; unfortunately without suitable

14

323   analytical method or measurements. The presence of Gd-dominant monazite with 42.5 wt%

324   Gd_2O_3 and empirical formula $(Gd_{0.55}Y_{0.25}Dy_{0.1}Sm_{0.05}Nd_{0.05}Th_0Ca_0)(PO_4)$ is noted from alkali-

325   feldspar syenite pegmatite at the Myan Gyi mine, near Mogok, Myanmar (Kartashov, web data at

326   mineralienatlas.de; mindat.org); however, without any further information. The impressive REE

327   accumulations in lignite coals from the Russian Far East Pavlovka deposit contain fine-grained

328   authigenic unknown Gd- and Dy-dominant minerals (Seredin 1992). Several nano- to micro-sized

329   particles of Gd-Ti-Zr oxides with dominant Gd occupancy and 9–57 wt% Gd_2O_3 were identified

330   in the lunar regolith from Mare Crisium (Bogatikov et al. 2004; Mokhov et al. 2011). In addition,

331   an unnamed Gd-dominant mineral (Gd>Ce>La) close to the $Gd_2Ti_4O_{11}$ formula was noted from

332   fumaroles in the active Kudriavy Volcano, Kuril Islands, Russia (Bogatikov et al. 2004).

333   However, all the above-mentioned findings of possible Gd-dominant minerals need to be taken

334   and interpreted with caution, because the data were obtained using semi-quantitative EDX

335   analysis without appropriate analytical details. Furthermore, other analytical data (e.g., XRD,

336   micro-Raman) are lacking.

337

338   **Gd and MREE incorporation in monazite and xenotime**

339   A large amount of literature exists on the crystal chemistry of natural and synthetic monazite-

340   and xenotime-type structures with the general formula APO_4 (e.g., Mullica et al. 1990; Ni et al.

341   1995; Kolitsch and Holtstam 2004; Clavier et al. 2011; Muñoz and Rodríguez-Hernández 2018

342   and references therein). There is general consensus that the pure end-members containing larger,

343   nine-fold coordinating LREE cations crystallize with the monoclinic monazite-type structure,

344   whereas those members with smaller HREE+Y cations in eight-fold coordination have a

345   tetragonal xenotime- (or zircon)-type structure, and the boundary between these two

15

346   orthophosphate structure types usually lies between Gd and Tb (e.g., Ni et al. 1995; Gratz and

347   Heinrich 1998; Hay et al. 2013; Rodriguez-Liviano et al. 2013). Thus, Tb is the largest REE

348   cation that the xenotime-type structure accommodates. However, the dimorphism of Gd- to Ho-

349   phosphates exists and depends on the conditions of formation, mainly the temperature of

350   precipitation, REE precursor, and pH of the solution (Kolitsch and Holtstam 2004; Boakye et al.

351   2008; Rodriguez-Liviano et al. 2013).

352   Monazite-group minerals from Zimná Voda, along with the significant Gd content, also

353   exhibit overall LREE>HREE signature, whereas xenotime is mostly Y-dominant and has

354   HREE>LREE signature. It suggests the substantial incorporation of Gd into both REE-selective

355   structures. These findings confirm the aforementioned earlier studies of differently-sized REE^{3+}

356   substitution in $REEPO_4$ solid solutions and the stabilization of the Gd-rich orthophosphate with

357   xenotime-type structure by substitution of the rest of the A-site cations for smaller HREE+Y and

358   vice versa (Mullica et al. 1986, 1990; Gratz and Heinrich 1998; Rodriguez-Liviano et al. 2013).

359   Conclusively, the stabilization of monazite- vs. xenotime-type structure of the natural $REEPO_4$

360   species depends on the average REE^{3+} ionic radius (Kolitsch and Holtstam 2004). In addition, the

361   xenotime-type structure of synthetic Gd-dominant phosphate doped by Tb, Y, Er, and Yb has

362   been documented by earlier studies (Mullica et al. 1986, 1990; Gratz and Heinrich 1998).

363   Moreover, the synthesis of pure $GdPO_4$ nanoparticles with tetragonal structure, has also been

364   previously reported (Rodriguez-Liviano et al. 2013). However, the possible impact on the

365   structural stability of commonly observed impurities, e.g., Th, U, Ca, Si, and S (cf. Demartin et

366   al. 1991a, 1991b; Förster 1998a, 1998b; Kolitsch and Holtstam 2004; Ondrejka et al. 2007;

367   Clavier et al. 2011) in the Zimná Voda MGM and XGM is probably not important, since the

368   concentrations of these elements are negligible (Supplementary Tables 5 and 6). Only As

369 concentration in some Gd-rich xenotimes are slightly higher than average ($\leq$0.045 apfu As),

370 which could result in similar stabilization effects toward the xenotime-type structure and suggests

371 that the behavior of the REEAsO$_4$ compound is different from those of the REEPO$_4$ compounds

372 (cf. Kolitsch and Holtstam 2004 and references therein).

373

374 **Origin of Gd and MREE enrichment**

375   The reported selective enrichment of Gd and other MREE in REE-U-Au vein mineralization

376 at Zimná Voda is an extremely rare process which occurred as a rather, localized anomaly in the

377 ZV-2 sample only, though in multiple thin sections. Other samples collected from the same site,

378 contain either a non- or less-fractionated composition of monazite-(Ce) and xenotime-(Y) with

379 respect to the ZV-2 sample. The dramatic increase of the local Gd concentration is linked to the

380 gradual decrease of the most common Ce (redox sensitive element) along with La, Pr, and Nd in

381 MGM. This cannot be fully explained solely by selective fractionation of REE due to the

382 oxidation of Ce^{3+} to Ce^{4+} and removal of CeO$_2$ from the solution (Fisher and Meyrowitz 1962;

383 Banfield and Eggleton 1989; Braun et al. 1990; Mayer et al. 2014; MacDonald et al. 2015;

384 Ondrejka et al. 2018), since the Ce negative anomaly did not develop in the chondrite-normalized

385 REE patterns of the studied minerals (Fig. 4). However, a coherent depletion on the first tetrad in

386 MGM developed instead. This indicates the possible appearance of a concave W-type tetrad

387 effect that occurs rarely, and together with the low Th content, supports the hypothesis of

388 hydrothermal crystallization from a low-temperature aqueous solution (e.g., Takahashi et al.

389 2002; Schandl and Gorton 2004; Zhao et al. 2010).

390   The compositional heterogeneity and variable enrichment in Gd and other individual REE,

391 particularly Sm in MGM, Dy, and Tb in xenotime-(Y), as well as Sm in hingganite-(Y) display

392   the expressive positive anomalies of Sm and Gd (less distinctive Dy and Tb) that are relative to

393   adjacent normalized values. This hump in MREE (a convex shape or "MREE bulge") is a

394   characteristic and remarkable feature of all late-crystallized REE minerals herein and most likely

395   results from a localized, yet strong progressive decoupling of LREE+HREE and MREE on

396   relatively small scales (cf. Anenburg 2020). The heterogeneous fluid composition on a micro

397   scale, as well as the development of variations in the local chemical environment responsible for

398   the strong enrichment of individual REE is most likely (cf. Franz et al. 2015). The textural-

399   compositional characteristics, which are generally dominant Ce and Y contents in the central

400   parts of the monazite and xenotime crystals, but lower in the outer parts and in younger veinlets

401   that cut the early-crystallized REE minerals, including the progressive fractionation trend toward

402   MREE in late-crystallized grains/domains, indicate the early crystallization of monazite-(Ce)

403   together with xenotime-(Y) I until Gd-predominance and MREE enrichment was achieved.

404   The reason for such extremely unusual MREE enrichment is not obvious; however, the

405   alteration of hypogene MREE-selective minerals (uraninite I, brannerite I ± fluorapatite, and

406   hingganite I) by late hydrothermal fluids or groundwater solutions can be responsible for such

407   REE remobilization and low-temperature MREE enrichment. The REE were probably mobilized

408   from these primary minerals, which are significant host phases for REE, especially when taking

409   into consideration their low REE content, yet high modal abundances. Here, uraninite, brannerite,

410   and fluorapatite show MREE-enriched chondrite-normalized patterns (Figs. 4a–4c). Such MREE-

411   enriched pattern is typical for hydrothermal apatite and differs from magmatic LREE-rich apatite

412   with a strong Eu anomaly (e.g., Krneta et al. 2017; Anenburg et al. 2020a). Primary hingganite I

413   also contributed to bulk MREE enrichment, even though it is rare in abundance and has a high

414   total REE content and distinct MREE-enriched pattern (Fig. 4h). During uraninite I precipitation,

18

415   the value of ionic radius of U^{4+} under reducing conditions in eight-fold coordination (1.00 Å) is

416   similar to those of trivalent Gd (1.05 Å) and Tb (1.04 Å) (Shannon 1976). Therefore, in

417   comparison with other REE, Gd^{3+} may have similar crystal-chemical properties as U^{4+} (cf.

418   Hidaka et al. 1992; Mercadier et al. 2011; Alexandre et al. 2015a, 2015b; Corcoran and Simonetti

419   2020). The chondrite-normalized REE patterns of uraninite from various occurrences, e.g., from

420   Shinkolobwe in the DR Congo; Orphan in Arizona, USA; Schwartzwalder in Colorado, USA;

421   Great Bear Lake in Canada; Morogoro in Tanzania; Roode pegmatite in Norway; and Jáchymov

422   in the Czech Republic show coinciding enrichment of MREE with a maximum at Gd or Tb

423   (Hidaka et al. 1992; Plášil et al. 2014; Alexandre et al. 2015a, 2015b; Balboni et al. 2017;

424   Corcoran and Simonetti 2020). In addition, most of the REE patterns of the aforementioned

425   common uraninites show an M-type tetrad effect with or without the Eu negative anomaly, which

426   is consistent with the REE pattern of uraninite I at Zimná Voda and linked with the non-

427   CHARAC behavior and genesis of uranium ore. Considering the occurrence of M-type tetrad

428   effect in the REE pattern of evolved granites-pegmatites and associated hydrothermal ore

429   deposits (Masuda et al. 1987; Irber 1999; Badanina et al. 2006; Peretyazhko and Savina 2010), it

430   is likely that hypogene uraninite I and particularly xenotime I show an inherited geochemical

431   signature of genetically-related Permian rare-metal Li–F granites of the Gemeric Unit, where the

432   whole-rock M-type tetrad effect and a high volatile flux is clearly documented (Broska and Kubiš

433   2018). The mechanism of the tetrad effect formation still remains unclear; however, it is

434   connected evidently to fluorine-controlled complexing in highly evolved ligand-rich

435   environments (e.g., Irber 1999; Masau et al. 2002; Veksler et al. 2005; Badanina et al. 2006;

436   Čopjaková et al. 2015).

437   The common, yet quantitatively variable presence of fluorapatite in all REE-U-(Au)-rich

438   quartz vein occurrences in the Gemeric Unit (Prakovce - Zimná Voda, Čučma - Majerská Valley,

439   Hnilec - Peklisko; Rojkovič et al. 1997, 1999; Števko et al. 2014; Ferenc et al. 2017; 2021; our

440   results) documents such a F-rich fluid environment. However, in Gd-dominant monazite with the

441   most pronounced W-type tetrad effect (Fig. 4e), a considerable depletion in La, Ce, and Pr, as

442   well as the enrichment of Sm and Gd seem to indicate a gradual development toward late-

443   crystallized mineral phases during low-temperature precipitation from aqueous fluids. Moreover,

444   the progressive flattening of pronounced M-type HREE pattern of xenotime I is clearly visible in

445   xenotime II and can also be attributed to late crystallization from aqueous fluids. Alternatively, or

446   even additionally, the potential source of P, Be and MREE-enrichment could be from

447   (meta)sedimentary host rocks associated with organic matter (cf. Kidder and Eddy-Dilek 1994;

448   Repina 2010; Franz et al. 2015).

449   In summary, the REE were released during the alteration of primary REE-bearing minerals,

450   the first generation of uraninite, brannerite, fluorapatite, monazite-(Ce), xenotime-(Y), and

451   hingganite-(Y). The REE budget shows the initial MREE-rich pattern that reflects the MREE-

452   selective behavior of altered minerals. The promoted crystallization of early monazite-(Ce)

453   selectively decreases the LREE content in the REE budget, whereas early crystallization of

454   xenotime I decreases the Y + HREE content. Since none of the MREE-selective minerals (e.g.,

455   young apatite, fluorite, titanite, and calcite) precipitate during this stage, the fluid becomes more

456   enriched in MREE and results in localized Gd±(MREE) predominance. However, this scenario is

457   likely only in an isochemical system; even local mass transport on a small spatial scale must

458   occur during precipitation. These findings suggest the localized process in a chemically near-

459   closed system where the circulation of fluids is limited. A similar scenario of core to rim (Y +

460   HREE)/LREE ratio development during garnet growth was described from A-type granite in the

461   Pre-Variscan Brno Batholith (Hönig et al. 2014).

462   One interesting aspect that emerged from our data is the clear connection of Gd (MREE)

463   enrichment with uranium ore and the subsequent alteration of uraninite and brannerite. The

464   genesis of lepersonnite-(Gd) is related to U-rich solutions and occurs in close proximity to altered

465   uraninite (cf. Finch and Ewing 1992). Likewise, the REE patterns for the Australian Proterozoic

466   U deposits (McLennan and Taylor 1979, Fisher et al. 2013) show a characteristic enrichment in

467   MREE and significant LREE depletion (cf. Franz et al. 2015). These data, along with our results,

468   suggest that the significant fractionation of REE with selective enrichment of MREE, particularly

469   Gd, can occur via alteration and leaching of uraninite ± fluorapatite ore by low-temperature, F-

470   rich aqueous fluids.

471

472   IMPLICATIONS

473   Lanthanoids represent essential elements of modern technology. Consequently, understanding

474   their behavior and precipitation conditions in natural systems, including MREE (Sm, Eu, Gd, Tb,

475   Dy), is crucial for their exploration and potential exploitation. This study focuses on a very

476   unusual assemblage of Gd (MREE)-rich minerals formed during the interaction of primary

477   minerals with low-T hydrothermal fluids. Such progressive development of Gd (MREE)

478   enrichment is a poorly-described process in nature. Nonetheless, the detailed microanalytical and

479   spectroscopic data, along with the microtextural observations reported here, provide evidence for

480   gradual remobilization-fractionation of U+REE in aqueous media. This study also demonstrated

481   the continuous evolution of the W-type tetrad effect from REE patterns without tetrad effect to

482   the well-developed W-type tetrad effect during the crystallization of monazite towards

21

483   Ce→Nd→Sm→Gd species. Similarly, the evolution from the REE patterns with well-developed

484   M-type tetrad effect to the patterns with less pronounced or no M-type tetrad effect is

485   documented during xenotime crystallization towards Y→Gd species. This clearly indicates that

486   the W-type tetrad effect gradually develops during progressive precipitation from the aqueous

487   media and associated processes, and thus the pattern gradates to the late and low-temperature

488   hydrothermal stage. The primary monazite-(Ce), xenotime-(Y), and hingganite-(Y) were partially

489   replaced by the assemblage of Gd-(MREE)-rich minerals during the interaction with F-rich

490   fluids. Middle REE generally do not comprise any mineral end-members and are considered to be

491   consistently present at low concentrations when compared to their LREE or HREE counterparts.

492   This study shows that low-T hydrothermal alteration and replacement reactions of MREE-

493   selective, but nominally REE-free minerals, e.g., uraninite, brannerite, and fluorapatite, can

494   produce an enhanced MREE signature in chemically-closed systems. Moreover, localized Gd-

495   rich environment remains an important direction for future research.

496   Finally, Gd-rich, and Gd-dominant minerals are quite rare in nature and thus of high

497   importance, since they often indicate extreme compositional regimes (e.g., Anenburg 2020). The

498   mineral with the composition of "monazite-(Gd)" reported here most likely represents the last

499   missing REE-dominant orthophosphate of the MGM in nature, since the other potential

500   lanthanoids Pr, Eu and Pm are three of the least abundant lanthanoids in the Earth's crust and

501   other Tb to Dy have ionic radii that are preferentially accommodated in the xenotime structure.

502   Moreover, our results show an existence of natural Gd-dominant xenotime, third member

503   together with xenotime-(Y) and xenotime-(Yb). Consequently, future investigation may complete

504   the list of already known members of MGM and XGM.

505

FIGURE 1. (a) Simplified geological-tectonic sketch-map of the Western Carpathians. **(b)** A geological map of the studied area (modified after Bajaník et al. 1984). **(c)** A close-up view on the veins, alteration and host rocks (modified after Donát et al. 2000).

803

FIGURE 2. BSE images of uraninite + brannerite textures and generations and flurorapatite from the Zimná Voda REE-U-Au mineralization. (**a**) Large botryoidal aggregates of uraninite I (Urn I) with globular microstructure showing numerous desiccation cracks and cavities filled with brannerite I (Bnr I). Uraninite II (Urn II) forms altered rim around uraninite I. Newly-formed uraninite III (Urn III) forms scattered crystals in the proximity of Urn I. Other secondary minerals are uranyl arsenates-phosphates (U-As-P). (**b**) Fractured uraninite I (Urn I) with altered rim of uraninite II (Urn II) in association with gersdorffite (Gdf) and quartz (Qz). (**c**) Fractured globular uraninite I (Urn I) with altered inner domains (Urn II) in quartz (Qz). (**d**) Globular aggregate of uraninite I (Urn I) and its secondary generations consisting of altered rim, inner altered domains (Urn II), and newly-formed crystals (Urn III), associated with secondary uranyl arsenates-phosphates (U-As-P) and quartz (Qz). (**e**) Large aggregates of brannerite I (Bnr I) in association with gold (Au), uraninite I (Urn I) and uranyl arsenates-phosphates (U-As-P). (**f**) Large aggregates of brannerite I (Bnr I), altered domains of brannerite II (Bnr II) associated with uraninite I (Urn I) and quartz (Qz). (**g**) Primary fluorapatite (Fap) scattered in quartz (Qz) and muscovite (Ms). Other minerals are xenotime-(Y) (Xtm), uraninite III (Urn III), and pharmacosiderite (Pmsd).

820

821   **FIGURE 3.** (**a, d**) BSE images and false color X-ray mapping showing the distribution of

822   chemical elements in uraninite aggregate (**b**–**c**), MGM–xenotime-(Y) (**e**–**o**) and hingganite-(Y)

823   (**p-r**). Images **j**–**o** are the same as rotated Fig. 5g and images **r**–**s** are the same as Fig. 5h.

824

825   **FIGURE 4.** Fitted chondrite-normalized REE patterns of minerals from sample ZV-2. Tetrad

826   effect parameters according to Minami and Masuda (1997). Chondrite values are from Barrat et

827   al. (2012).

828

829   **FIGURE 5.** BSE images of REE minerals from the Zimná voda REE-U-Au mineralization. (**a**)

830   Compositionally-heterogeneous aggregate of xenotime I (Xtm I) and remobilized Gd-rich

831   xenotime II (Xtm II) associated with monazite-(Ce) (Mnz-Ce) and uraninite (Urn) in quartz-

832   muscovite gangue (Qz + Ms). (**b**) Xenotime I (Xtm I) with marginal domains rich in Gd (Xtm II)

833   with monazite-(Nd) (Mnz-Nd) and monazite-(Sm) (Mnz-Sm). (**c**) Monazite-(Nd) (Mnz-Nd) in

834   association with xenotime I (Xtm I) with rims of Gd-rich xenotime II (Xtm II) and numerous

835   inclusions of uraninite (Urn) in quartz (Qz). (**d**) Heterogeneous aggregate of monazite-(Sm)

836   (Mnz-Sm) and "monazite-(Gd)" (Mnz-Gd) with xenotime I (Xtm I), Gd-rich xenotime II (Xtm II)

837   and uranyl arsenates-phosphates (U-As-P) in quartz-muscovite gangue (Qz + Ms). (**e**) Large and

838   compositionally-heterogeneous aggregate of xenotime I + II (Xtm I + II) with numerous

839   inclusions of uranyl arsenates-phosphates (U-As-P) in quartz (Qz). (**f**) Monazite-(Nd) (Mnz-Nd)

840   and xenotime I with Gd-rich xenotime II outer domains (Xtm II) in quartz (Qz) associated with

841   uranyl arsenates-phosphates (U-As-P). (**g**) Heterogeneous aggregate of xenotime I (Xtm I)

842   penetrated by xenotime II vein (Xtm II) in association with uranyl arsenates-phosphates (U-As-P)

843   in scorodite (Scd) and quartz (Qz). (**h**) Cracked crystal of hingganite I (Hin I) with Gd-rich

844   domains of hingganite II (Hin II) in quartz (Qz) gangue.

845
