19

20   **Abstract**

21   Society annually consumes 250% more Sb relative to the year 1960 and a sustainable

22   supply of antimony depends critically on understanding the precipitation mechanism of

23   stibnite (Sb_2S_3) that is the globally predominant source of this important technology metal.

24   Previous solubility studies revealed that antimony is transported in mesothermal

25   hydrothermal fluids mainly as thioantimonite ($H_2Sb_2S_4$, $HSb_2S_4^-$, $Sb_2S_4^{2-}$) and

26   hydroxothioantimonite ($Sb_2S_2(OH)_2$). Thioantimonite can transform to

27   hydroxothioantimonite as the decline of H_2S concentration. However, whether this

28   transition occurs in hydrothermal systems and its role in stibnite precipitation are unknown.

29   In this work, bulk Sb isotope measurements for stibnite from the world's largest Sb deposit

30   in Xikuangshan China were conducted to address ore fluid evolution and stibnite

31   precipitation mechanisms. The abundance of the stable antimony isotopes ^{121}Sb and ^{123}Sb

32   were measured in stibnite from the Xikuangshan orebodies and reported as $\delta^{123}Sb$. The

33      $\delta^{123}Sb$ values show a trend of decreasing first and then increasing from proximal to distal

34   parts of orebodies. This reveals that ^{123}Sb had been preferentially partitioned from the ore

35   fluid into stibnite first, then ^{123}Sb remained preferentially dissolved in the ore fluid. These

36   data indicate that the dominant Sb-complex transforms to $Sb_2S_2(OH)_2$ from $H_2Sb_2S_4$ with

37   consuming of H_2S. Speciation diagram considerations indicate that stibnite precipitation

38   from the ore fluid was controlled by two telescoped processes: 1) boiling of the ore fluid

39   induced a decrease in H_2S that reduced the solubility of $H_2Sb_2S_4$, and 2) subsequent cooling

40   that induced a decrease in the solubility of $Sb_2S_2(OH)_2$. This study highlights that

41   understanding the controls of Sb isotope fractionation is critical to constrain fluid evolution

42   and stibnite precipitation mechanisms in Sb-rich mineral systems. In particular, the stable Sb

43   complex in the hydrothermal ore fluid may change during fluid evolution and affect the

44   isotope fractionation mechanism.

47

48   **1. Introduction**

49   Antimony is a critical mineral commodity essentially for a wide variety of products

50   including flame retardants and alloys for batteries, plain bearings, and solders (Schulz et al.,

51   2018). This metal is found in more than 100 minerals in a variety of deposits. The most

52   common antimony ore mineral is stibnite (Sb_2S_3) occurring as fault-controlled or strata-

53   bound orebodies (Hofstra et al., 2013; Xie, 2018; Fu et al., 2020d). Simple stibnite-bearing

54   quartz ± carbonate veins account for most of the current and recent mine production.

55   Antimony resources are unevenly distributed globally (Fig. 1). The majority of identified Sb

56   resources are located in China who leads global production (Schulz et al., 2018; Yu et al.,

57   2022). Society annually consumes 250 % more Sb relative to the year 1960, while the

58   antimony production continued to decline (Schulz et al., 2018). A sustainable supply of

59   antimony depends critically on understanding the ore fluid evolution and stibnite

60   precipitation mechanisms in hydrothermal Sb deposits.

61   Antimony displays a wide range of oxidation states (Sb^{3-} to Sb^{5+}), most of which are

62   present in trivalent and pentavalent forms in crustal fluids (Zotov et al., 2003; Fu et al.,

63   2020d). Under surface oxidizing conditions, Sb^{5+} may be predominant, and Sb-bearing

64   hydrothermal fluids mainly contain Sb^{3+} (Fu et al., 2020d). In hydrothermal fluids, Sb is

65   transported mainly as thioantimonite ($H_2Sb_2S_4$, $HSb_2S_4^-$, $Sb_2S_4^{2-}$), hydroxothioantimonite

66   ($Sb_2S_2(OH)_2^0$), hydroxide complexes ($Sb(OH)_2^+$, $Sb(OH)_3^0$, and $Sb(OH)_4^-$), chloride

67   complexes, and carbonate or bicarbonate species (Krupp, 1988; Hagemann and Luders,

68   2003; Zotov et al., 2003; Wilson et al., 2007; Fu et al., 2020d). Given that (1) hydroxide

69   complexes are formed in sulfur-free system, (2) chloride complexes are unimportant in

70   antimony speciation except in extremely acid, chloride-rich solutions, and (3) carbonate or

71   bicarbonate species are unimportant in antimony transport, thioantimonite and

72   hydroxothioantimonite are thus likely to be dominant in ore fluids (Krupp, 1988; Williams-

73   Jones and Norman, 1997). In mesothermal ore fluids, solubility experimental studies

74   revealed the distribution of antimony species as a function of pH. Hydroxothioantimonite

75   controls antimony transport at acidic pH, and thioantimonite is dominant at intermediate to

76   alkaline pH (Krupp, 1988). In addition, the solubility experimental studies indicated that

77    $H_2Sb_2S_4$ can transform to $Sb_2S_2(OH)_2$ with the consuming of H_2S (Krupp, 1988; Zotov et al.,

78   2003). Previous research showed that different processes can decrease the solubility of

79   corresponding Sb complexes in aqueous hydrogen sulfide solutions, e.g., consuming of H_2S

80   can induce the stibnite precipitation from thioantimonite, while decreasing temperature can

81   decrease the solubility of both thioantimonite and hydroxothioantimonite (Krupp, 1988;

82   Zotov et al., 2003). Both pH change and cooling have been shown to be the causes of

83   stibnite deposition in geothermal power stations in New Zealand (Wilson et al., 2007).

84   Numerous fluid inclusion studies have been carried out on hydrothermal Sb-rich deposits

85   and proposed various models proposed for the major geological processes, including fluid

86   cooling, fluid boiling, fluid mixing, and fluid-rock interaction (Hagemann and Luders, 2003;

87   Su et al., 2009; Muntean et al., 2011; Hu and Peng, 2018; Xie, 2018; Deng et al., 2020b; Fu

88   et al., 2020c; Qiu et al., 2020; Voisey et al., 2020; Wu et al., 2021; Yu et al., 2021). These

89   studies inferred these geological processes decrease the solubility of Sb complexes and

90   control stibnite precipitation. It's clear that the concentration of H_2S will change with the

91   precipitation of stibnite, likely inducing the transition of dominant Sb complexes. However,

92   none of these studies focus on the transition of dominant Sb complexes as fluid evolution

93   and explore its role in stibnite precipitation.

94   Several studies have underpinned the crucial importance of metal isotope tracing as a

95   prerequisite to constrain the evolution of large-scale ore-forming systems (Mathur et al.,

96   2005; Toutain et al., 2008; Kelley et al., 2009; Qiu et al., 2017; Gao et al., 2018; Mathur et

97   al., 2018; Ohmoto, 2018; Zhu et al., 2018; Li et al., 2019; Wang et al., 2020a; Yu et al.,

98   2020). The application of the Sb isotope system as a process tracer for ore deposits is in its

99   infancy (Rouxel et al., 2003; Zhai et al., 2021). Although the dominant Sb species involved

100   and their associated isotope fractionations are poorly understood, initial studies explored the

101   range of Sb isotope compositions for natural samples (Rouxel et al., 2003; Wen et al., 2018;

102   Kaufmann et al., 2021), fractionation mechanisms (Lobo et al., 2012; Resongles et al., 2015;

103   Wen et al., 2018), and mineralization processes (Zhai et al., 2021). Reduction processes

104   from Sb^{5+} to Sb^{3+} exert a strong fractionation of 0.9 ‰ (Rouxel et al., 2003). Lighter Sb

105   isotopes preferentially partition into the Sb^{3+} phase, whereas heavier Sb isotopes remain in

106   the Sb^{5+} phase (Rouxel et al., 2003). Additionally, Sb isotope fractionation can be caused by

107   evaporation and precipitation of Sb during Sb-containing waste combustion and Sb ore

108   smelting (Tanimizu et al., 2011). Zhai et al. (2021) proposed that separation of stibnite from

109   an Sb-bearing fluid related to reaction kinetics as a cause for Sb isotope fractionation. These

110   studies demonstrate that the Sb isotope have the potential to be used as a process tracer for

111   the fluid evolution of large Sb ore systems.

112   The Xikuangshan deposit in Hunan Province, China, is the world's largest Sb deposit,

113   which has supplied more than half of all globally mined Sb (Yang et al., 2006; Deng and

114   Wang, 2016; Hu et al., 2017; Goldfarb et al., 2019; Fu et al., 2020a; Luo et al., 2020). It

115   provides a natural case to better understand the ore fluid evolution and stibnite precipitation

116   mechanisms in hydrothermal Sb deposits. In this study, we report δ^{123}Sb isotope values for

117   stibnite from the proximal steeply-dipping orebodies. This new dataset can be compared

118   with existing δ^{123}Sb isotope values from the distal shallowly-dipping orebodies to address ore

119   fluid evolution and stibnite precipitation mechanisms.

120

121   **2. Geology of the Xikuangshan Sb deposit**

122   The Xiangzhong province of China hosts the world's largest Sb reserves in the world,

123   with over 171 known antimony mineral deposits and 2.7 Mt Sb reserves (Deng et al., 2017;

124   Hu and Peng, 2018; Wang et al., 2020b; Fu et al., 2022; Yan et al., 2022). Estimates of

125   historic mining activity indicate that approximately 1 Mt of Sb have been produced from the

126   Xikuangshan Sb deposit beginning in the 16th century and pre-mining reserves are 2.5 Mt at

127   an average Sb grade of 4.0 wt. % (Fu et al., 2020c). The Sb resource of the deposit is mined

128   by four mines, referred to as Laokuangshan and Tongjiayuan mines in the North Ore Block

129   and Wuhua and Feishuiyan mines in the South Ore Block (Fig. 2A). The mining area is

130   dominated by Middle Devonian to Lower Carboniferous carbonate rocks and minor shale,

131   which is locally interbedded with siltstone and argillite and formed a NE- striking anticline.

132   An Early Cretaceous (127.8 Ma; biotite K-Ar) lamprophyre dike aligned in the NE direction

133   was emplaced into the strata in the eastern part of the mine (Wu and Hu, 2000). It exhibits a

134   calc-alkaline affinity, with geochemical signatures implying it was derived from enriched

135   lithospheric mantle (Xie et al., 2001; Hu and Peng, 2018). A series of broadly parallel NE-

136   striking normal faults crosscut the mine and were cut by later NW-striking strike-slip faults

137   (Fig. 2A).

138   Much of the Sb resource in the Xikuangshan deposit is hosted in the footwall of the

139   NE-striking fault F75. It hosts three types of orebodies: (1) steeply-dipping orebodies along

140   the footwall of the major deep-seated fault F75, (2) shallowly-dipping orebodies within the

141   strata controlled by a NE- striking anticline, and (3) transitional zones between the steeply-

142   dipping and shallowly-dipping orebodies (Fig. 2B). All of the three types of orebodies show

143   a southward plunge, leading to a relatively deeper mining depth in the South Ore Block of

144   the Xikuangshan deposit. The ore-bearing zones are commonly hosted within the Devonian

145   silicified limestone (Fig. 3). Hydrothermal alteration of the three types of orebodies is

146   similar in appearance and mineral assemblages. It is characterized by quartz alteration and

147   carbonate alteration (Figs. 3A, 3C, 4A), as well as local fluorite alteration. Ores in the

148   Xikuangshan deposit are divided into quartz-stibnite and calcite-quartz-stibnite vein-style

149   mineralization and disseminated minor barite-quartz-stibnite and fluorite-quartz-stibnite

150   veinlet-style mineralization around the vein-style mineralization (Fig. 4). In general, the

151   shallowly-dipping orebodies are dominated by the quartz-stibnite ores (Fig. 4C), while the

152   steeply-dipping orebodies are dominated by the calcite-quartz-stibnite ores (Fig. 4D).

153   Optical microscopic investigation revealed that stibnite is the dominant sulfide mineral, with

154   quartz, calcite, fluorite, and barite as gangue minerals (Fig. 5). Stibnite crystals from the

155   shallowly-dipping and steeply-dipping orebodies are identical in mineralogy assemblages.

156   Their size varies largely, ranging from tens of microns to several centimeters. Most of them

157   are anhedral, growing along the margin of the quartz and calcite (Fig. 5A-C). Euhedral

158   needle-shaped crystals in limestone wall rock and calcite grains are also visible (Figs. 4B,

159   5D). Detrital zircons separated from the altered host rocks from the Xikuangshan deposit

160   yielded (U-Th)/He ages ranging from 156 to 117 Ma, constraining the antimony event to

161   late Mesozoic (Fu et al., 2020a). Microthermometry data for fluid inclusions hosted in

162   stibnite from both types of orebodies reveal similar ore fluid conditions. The

163   homogenization temperatures of stibnite from the shallowly-dipping orebodies range from

164   105 to 305 °C (averaging at 194 °C), with an average salinity of 6.0 wt.% NaCl equiv. For

165   fluid inclusions within stibnite in the steeply-dipping orebodies, their homogenization

166   temperatures range from 163 to 218 °C (averaging at 192 °C) with an average salinity of 8.1

167   wt.% NaCl equiv. (Lin, 2014; Hu and Peng, 2018; Zhang, 2018). Integrated He-Ar-C-O-Sr

168   isotopic data indicate that the ore fluids are modified air-saturated meteoric water (Fu et al.,

169   2022). The concentrations of Sb in different types of rocks in the region and S isotope show

170   that most of the Sb was derived from the Neoproterozoic basement rocks (Fu et al., 2022;

171   Long et al., 2022).

172

173   **3. Sampling strategy and methods**

174   Zhai et al. (2021) measured Sb isotope abundances in stibnite sampled from the

175   shallowly-dipping orebodies and the transitional zones between the steeply-dipping and

176   shallowly-dipping orebodies. To further understand the ore fluid evolution and stibnite

177   precipitation mechanisms in the Xikuangshan deposit, the steeply-dipping orebodies are

178   sampled in this study. Twenty-six samples spanning all the main steeply-dipping orebodies

179   at different levels in the Feishuiyan mine at the Xikuangshan deposit were collected (Fig.

180   6A). Optical microscopic investigation of all samples indicated that no sulfide inclusions

181   were present in the analyzed stibnite (Fig. 5).

182   Stibnite separation was done by using standard methods of concentration including

183   crushing, heavy liquids, and magnetic separation at Beijing Precambrian Inc., Beijing,

184   China. The purity of all stibnite concentrates was assessed microscopically prior to isotopic

185   analysis to ensure they were monomineralic and not oxidized. Stibnite aliquot purities were

186   commonly ≥ 99% and never < 95%. Antimony isotope compositions of the 26 samples were

187   measured on a Thermo Scientific Neptune Plus MC-ICP-MS in low resolution mode, wet

188   plasma using Ni cones at Pennsylvania State University. The full analytical procedures are

189   provided in Zhai et al. (2021). Alfa Star verified acids were used and total blanks of these

190   acids are certified at less than 0.01 ppb Sb. Approximately 30-50 mg of stibnite was

191   dissolved for 18 hours in 15 ml telfon beakers containing 2 ml of aquaregia. Complete

192   dissolution of materials was visually confirmed. Samples were diluted with 2 % nitric acid

193   with 100 ppb NIST 3161 Sn internal standard. Mass bias was corrected using $^{124}Sn/^{116}Sn$

194   and samples were bracketed with NIST 3102a standard. One block of 35 ratios with on peak

195   blank subtraction with an integration time of 12s was conducted as part of the measurement

196   protocol. The mass of ^{123}Sb was set in the standard between 5-6 volts (solutions at 100 ppb),

197   all measurements reported are within 20% matching of this voltage. The variation of the

198   bracketing the standard throughout the run is considered the largest source of error and it

199   varied 0.018 ‰ (2SD). The majority of the samples were duplicated and fall within the

200   reported error (Table 1). At this moment no stibnite standards are reported as a means of

201   QA/QC, thus a High Purity ICPMS standard which have been now measured over 15 times

202   was used. The internal stibnite standard yields δ^{123}Sb values of 0.336 ‰ and 0.338 ‰,

203   which are consistent with the standard analyses of 0.31 ± 0.02 ‰ in Zhai et al. (2021).

204

205   **4. Results and previous data**

206   The Sb isotope compositions of stibnite from this study and from the study of Zhai et

207   al. (2021) are shown in Fig. 6A and listed in Table 1. Previous 39 Sb isotope measurements

208   from Xikuangshan Zhai et al. (2021) were conducted either using the same analysis

209   procedures at Pennsylvania State University as these new data (1/39 analyses) or at Rutgers

210   University (39/39 analyses) and Washington State University (1/39 analyses), where cross-

211   checking of standards and identical samples allows direct comparison of isotope ratios of

212   samples.

213   The δ^{123}Sb values for samples from the steeply-dipping orebodies in the Feishuiyan

214   mine range from +0.483 to +0.988 ‰ and decrease systematically from deep (proximal) to

215   shallow (distal) levels in the system. Stibnite from the -604 m, -468 m, -192 m, -142 m, and -

216   106 m levels of the steeply-dipping orebody yielded averaged δ^{123}Sb values of +0.958 ‰ ±

217   0.086 ‰ (n=2), +0.767 ‰ ± 0.043 ‰ (n=6), +0.590 ‰ ± 0.091 ‰ (n=7), +0.559 ‰ ±

218   0.071 ‰ (n=6), and +0.534 ‰ ± 0.079 ‰ (n=5) (2σ), respectively (Fig. 6B; Table 1). Zhai

219   et al. (2021) measured Sb isotope abundances in stibnite sampled from the shallowly-

220   dipping orebodies in the Feishuiyan mine in the South Ore Block. The δ^{123}Sb values of

221   stibnite sampled from the shallowly-dipping orebody range from +0.21 ‰ to +0.86 ‰, but

222   show a systematical increase from proximal to distal ores in the system (Fig. 6B; Table 1).

223   The shallowly-dipping orebodies and the transitional zones between the steeply-dipping and

224   shallowly-dipping orebodies in the North Ore Block were also measured by Zhai et al.

225   (2021). Those authors reported the δ^{123}Sb values ranging from 0.30 ‰ to 0.62 ‰ at the

226   transitional zones. Similar to the South Ore Block, stibnite from the shallowly-dipping

227   orebodies in the North Ore Block show an increase from proximal to distal ores in the

228   system, ranging from -0.27 ‰ to +0.70 ‰ (Fig. 6B; Table 1)

229

230   **5. Antimony isotopic fractionation model**

231   Some geological processes that may lead to the variation in δ^{123}Sb values of stibnite

232   reported here and from Zhai et al. (2021) in the Xikuangshan deposit include 1) mixing of

233   hydrothermal fluid with an external-derived fluid (e.g., meteoric water; Neyedley et al.,

234   2017; Qiu et al., 2017) and 2) isotope fractionation during hydrothermal processes (e.g.,

235   redox change, ore precipitation; Moynier et al., 2017; Teng, 2017; Deng et al., 2020a; Wang

236   et al., 2020a; Qiu et al., 2021). Given the extremely low Sb concentration in meteoric water,

237   the effect of external-derived fluid mixing on the Sb isotopic composition in the ore system

238   can be easily excluded. Likewise, unaltered host rocks show low Sb concentration (Fu et al.,

239   2020b), implying that the fluid-rock interaction cannot modify the Sb isotopic composition

240   of the system. Considering that the reduced sulfur complexes (thioantimonite and

241   hydroxothioantimonite) are dominant agents for transporting Sb in the hydrothermal fluids

242   in Xikuangshan, it follows that S and Sb could originate from the same source (Long et al.,

243   2022). As evidenced by the relatively homogeneous δ^{34}S of stibnite (average of 8.0 ± 0.5 ‰,

244   2σ; Fu et al., 2020c; Long et al., 2022 and references therein), fluid mixing may not be the

245   cause of variation in δ^{123}Sb values. The most reasonable explanation for the observed

246   variation in δ^{123}Sb values of stibnite are isotope fractionation during hydrothermal

247   processes.

248   A few studies explored possible causes of Sb isotopic fractionation in natural and

249   experimental settings by assessing the effects of redox reactions (Rouxel et al., 2003; Kendall

250   et al., 2017; Moynier et al., 2017) and kinetic Rayleigh fractionation (Watkins et al., 2017;

251   Wang et al., 2020a; Zhai et al., 2021). Rouxel et al. (2003) reported the significant Sb

252   isotopic fractionation of up to 0.9 ‰ in aqueous solutions during reduction of Sb^{5+} to Sb^{3+} in

253   two duplicate experiments. The effect of reduction on the observed variation of $\delta^{123}Sb$ values

254   in stibnite samples can be eliminated, considering that Sb^{3+} is the predominant ion species in

255   Sb-bearing hydrothermal fluids and Sb^{5+} mostly exist in surficial environments (Zotov et al.,

256   2003; Fu et al., 2020d). We propose that the systematic variability of $\delta^{123}Sb$ values in stibnite

257   in the Xikuangshan orebodies are best explained by Rayleigh fractionation during the

258   precipitation of stibnite from hydrothermal fluids. Rayleigh fractionation has been

259   demonstrated to be a potential factor that can lead to metal isotope fractionation of, for

260   example, copper (e.g., Gregory and Mathur, 2017), iron (e.g., Wang et al., 2018; Zhu et al.,

261   2018; Zhang et al., 2021), molybdenum (e.g., Hannah et al., 2007; Li et al., 2019), zinc (e.g.,

262   Mondillo et al., 2018), cadmium (e.g., Wen et al., 2016; Zhu et al., 2017), and lead (e.g.,

263   Gao et al., 2018) during the precipitation of sulfide minerals from hydrothermal fluids in

264   types of mineral systems. The Rayleigh fractionation model for Sb is illustrated in Fig. 6B as

265   determined by using the equations

266    $$\delta^{123}Sb_{Fl}^{F}= (\delta^{123}Sb_{Fl}^{F=1}+ 10^3) \times F^{\alpha-1} - 10^3 \quad (1)$$

267    $$\delta^{123}Sb_S = (\delta^{123}Sb_{Fl} + 10^3) \times \alpha - 10^3 \quad (2)$$

268   where Fl = ore-forming fluid, S = stibnite, $\delta^{123}Sb_{Fl}^{F=1}$ = initial Sb isotopic compositions, F =

269   the fraction of reactant remaining, α = fractionation factor. We use subscript 1 (F_1, S_1, α_1)

270   for the steeply-dipping orebody and transitional zone and subscript 2 (F_2, S_2, α_2) for the

271   shallowly-dipping orebody in the fractionation equations.

272   An Sb isotope fractionation model for the steeply-dipping and shallowly-dipping

273   orebodies is constructed by integrating the new data reported here and data in Zhai et al.

274   (2021) (Fig. 6). For the shallowly-dipping orebodies, an initial δ^{123}Sb value ($\delta^{123}Sb_{S2}^{F2=1}$) of -

275   0.16 ‰ ± 0.03 ‰ for stibnite is used based on the average δ^{123}Sb value of stibnite from the

276   most proximal samples of the shallowly-dipping orebodies. A final $\delta^{123}Sb_{S2}^{F2=0}$ value of 0.85

277   ‰ ± 0.01 ‰ for stibnite is used to model the most distal samples of the shallowly-dipping

278   orebodies. The fractionation factor α_2 is calculated as 0.99978 ± 0.00001. The initial δ^{123}Sb

279   value of the ore fluid ($\delta^{123}Sb_{Fl2}^{F2=1}$) that precipitated the shallowly-dipping orebodies is thus

280   calculated as 0.060 ‰ ± 0.011 ‰. Given that the hypogene ore-forming fluid ascended

281   along the major fault F75 and stibnite precipitated first from that fluid within the steeply-

282   dipping orebody and subsequently in the shallowly-dipping stratigraphically controlled

283   orebodies, we use a final δ^{123}Sb value of 0.060 ‰ ± 0.011 ‰ for the ore fluid ($\delta^{123}Sb_{Fl1}^{F1=0.34}$)

284   in the steeply-dipping orebodies. As the average δ^{123}Sb values from the deepest and

285   shallowest ore samples are 0.958 ‰ and 0.490 ‰, the initial and final δ^{123}Sb values

286   ($\delta^{123}Sb_{S1}^{F1=1}$ and $\delta^{123}Sb_{S1}^{F1=0}$) of stibnite in the steeply-dipping orebodies are calculated to be

287   0.960 ‰ ± 0.029 ‰ and 0.493 ‰ ± 0.002 ‰. The fractionation factor α_1 and the initial

288   δ^{123}Sb value of the ore fluid ($\delta^{123}Sb_{Fl1}^{F1=1}$) are calculated to be 1.00043 ± 0.00003 and 0.530

289   ‰ ± 0.016 ‰, respectively (Fig. 6B).

290

291   **6. Fluid evolution and precipitation mechanisms of ores**

292   Rayleigh fractionation modeling of Sb isotopic compositions from the steeply- and

293   shallowly-dipping orebodies in the Xikuangshan deposit reveals opposite trends in δ^{123}Sb

294   values during stibnite precipitation (Fig. 6B). This result is consistent with a difference in the

295   dominant Sb-complex dissolved in the ore fluid in different parts of the system. In

296   hydrothermal fluids, Sb^{3+} may be transported mainly as thioantimonite ($H_2Sb_2S_4$, $HSb_2S_4^-$,

297    $Sb_2S_4^{2-}$), hydroxothioantimonite ($Sb_2S_2(OH)_2$), hydroxide ($Sb(OH)_3$, $Sb(OH)_4^-$), and chloride

298   ($SbCl_3$, $SbCl_4^-$, and $SbCl_5^{2-}$) complexes (Krupp, 1988; Williams-Jones and Norman, 1997;

299   Hagemann and Luders, 2003). Previous studies of the Xikuangshan deposit reported that Sb

300   mineralization precipitated from a hydrothermal fluid with a salinity of 0.2-14.8 wt.% NaCl

301   equiv., and a slightly acidic to neutral pH (~5.5-6.5) over the temperature range 105-305 °C

302   (Lin, 2014; Hu and Peng, 2018; Zhang, 2018). For a hydrothermal fluid at those conditions,

303   thermodynamic calculations indicate that the dominant Sb complexes in the fluid are

304    $H_2Sb_2S_4$ and $Sb_2S_2(OH)_2$ (Fig. 6C). Although their associated isotope fractionations are

305   poorly understood, heavier isotope (^{123}Sb) is preferentially partitioned into the site with the

306   highest bond energy, which is demonstrated for many systems (Penniston-Dorland et al.,

307   2017). Bond energies of Sb-H (56.4 kcal/mol), Sb-S (90.5 kcal/mol), and Sb-O (102.8

308   kcal/mol) increase in turn (Luo, 2005), indicating that ^{123}Sb is preferentially complexed as

309   Sb-O, then Sb-S, and finally Sb-H during precipitation of stibnite (Sb_2S_3) from the

310   hydrothermal fluid. The Rayleigh fractionation model results reported here (Fig. 6B)

311   indicate that ^{123}Sb is preferentially partitioned into stibnite, indicating the dominant Sb

312   complex is $H_2Sb_2S_4$ in the fluid responsible for mineralization in the steeply-dipping

313   orebody, whereas ^{121}Sb is preferentially partitioned into stibnite in the shallowly-dipping

314   orebody indicating the dominant Sb complex is $Sb_2S_2(OH)_2$ in the fluid responsible for

315   mineralization in the shallowly-dipping orebody.

316   Precipitation of stibnite from an $H_2Sb_2S_4$-bearing fluid in the steeply-dipping orebody

317   would follow a decrease in activity of H_2S (aH_2S) in the fluid, as shown by the following

318   equation from Krupp (1988):

$$H_2Sb_2S_4 = Sb_2S_3 + H_2S \quad (3)$$
320   Boiling and wall rock sulfidation are major mechanisms to decrease the aH_2S. The modally-

321   minor amount of pyrite and arsenopyrite in the host rock at Xikuangshan rule out the

322   possibility of wall rock sulfidation. Thus, the most likely mechanism of ore precipitation in

323   the steeply-dipping orebodies was fluid boiling, which could have occurred by dramatic

324   pressure fluctuations through both localized fracture dilation and fluid ascent along the

325   major fault (Fig. 7; Voisey et al., 2020). Notably, as aH_2S decreases, $Sb_2S_2(OH)_2$ becomes

326   the dominant stable Sb complex in the fluid (path from point 1 through 2 in Fig. 6C),

327   wherein [121]Sb is preferentially partitioned into stibnite as it crystallizes from the fluid.

328   Precipitation of stibnite from the ore fluid can be described by the reaction:

$$Sb_2S_2(OH)_2 + H_2S = Sb_2S_3 + 2H_2O \quad (4)$$
330   which indicates that decreasing the aH_2S does not decrease the concentration of Sb in the

331   fluid but rather shifts the fluid-stable Sb complex to $Sb_2S_2(OH)_2$. Therefore, the most

332   plausible precipitation mechanism for the shallowly-dipping orebodies is a decrease in

333   temperature (path from point 2 through 3 in Fig. 6C). Cooling of the hypogene ore fluid can

334   occur by bringing deeply sourced fluids into colder wall rock or mixing with meteoric

335   waters. Published fluid inclusion data and H-O isotope data of quartz veins coeval with

336   stibnite indicate that meteoric and pore fluids was present in the host rocks for the

337   shallowing dipping orebodies prior to infiltration of the Sb-bearing ore fluid (Hu and Peng,

338   2018). This means that the fluid mixing with meteoric and pore fluids would have resulted

339   in cooling of the ore fluid and precipitation of stibnite in the shallowly-dipping orebodies

340   with the range of $\delta^{123}Sb$ values reported here (Figs. 6C, 7).

341

342   **7. Implications**

343   Transition of the dominant Sb complex from thioantimonite ($H_2Sb_2S_4$) to

344   hydroxothioantimonite ($Sb_2S_2(OH)_2$) in hydrothermal fluids occurs with consuming of H_2S.

345   The initial dominant Sb complex maybe $H_2Sb_2S_4$ in hydrothermal fluids. In this stage,

346   boiling of the ore fluid inducing a decrease in H_2S that reduced the solubility of $H_2Sb_2S_4$ is

347   the main precipitation mechanism. Meanwhile, ^{123}Sb is preferentially complexed as Sb-S,

348   showing a systematical decrease in $\delta^{123}Sb$ values. As consuming of H_2S, $Sb_2S_2(OH)_2$

349   becomes the dominant stable Sb complex in the fluid, wherein ^{121}Sb is preferentially

350   partitioned into stibnite as it crystallizes from the fluid. Precipitation of stibnite from the ore

351   fluid is triggered by fluid cooling. Our work shows that stable metal complex in the

352   hydrothermal ore fluid may change induced by fluid evolution and affect the isotope

353   fractionation and metal precipitation mechanisms.

587   **Figure captions**

588   Fig. 1. Map showing the global distribution of representative antimony deposits. Modified

589   after Deng et al. (2019) and Zhang et al. (2020).

590   Fig. 2. (A) Geological map of the world's largest Sb deposit in Xikuangshan (modified from

591   Fu et al., 2020b). (B) Cross section map of No. 41 exploration line (A-B) showing two types

592   of orebodies (modified from Zhai et al., 2021; Long et al., 2022)

593   Fig. 3. Underground exposures showing the Sb orebody hosted in the silicified limestone.

594   Antimony occurs chiefly as the stibnite from the quartz-stibnite vein (A, B) and calcite-

595   quartz-stibnite vein (C, D).

596   Fig. 4. Silicified limestone (A), euhedral stibnite in limestone (B), stibnite-quartz vein ore

597   (C) and stibnite-calcite-quartz vein ore (D).

598   Fig. 5. Mineral assemblages of the Sb ores. Anhedral stibnite along the margin of the quartz

599   and calcite (A-C) and euhedral needle-shaped crystals in calcite grains (D). Cal = calcite, Stb

600   = stibnite, Qz = quartz.

601   Fig. 6 (A) Schematic cross-section showing sample locations from this work and Zhai et al.

602   (2021). Note that the orebodies of the Xikuangshan deposit show a southward plunge,

603   inducing a relatively deeper mining depth in the southern part of the deposit. As a result, the

604   elevations of the samples represent positions projected on the cross-section rather than the

605   real elevations. (B) The Sb isotopic Rayleigh distillation model of the steeply-dipping and

606   shallowly-dipping orebodies of the Xikuangshan Sb deposit. The grey dots are from Zhai et

607   al. (2021). The initial δ^{123}Sb values of the hydrothermal fluid is defined to 0.530 ‰. The

608   fractionation factors (α_1 for steeply-dipping orebodies and α_2 for shallowly-dipping

609   orebodies) between stibnite and solution are 1.00043 and 0.99978. The δ^{123}Sb values of

610   stibnite change abruptly at the transitional zone. F means the fraction of reactant remaining.

611 (C) Speciation diagram of aqueous Sb species in hydrothermal fluids with superimposed Sb

612 fluid solubility contours. Bold lines indicate boundaries between aqueous Sb species. Circled

613 numbers indicate hypothetical points for illustrating fluid property changes. Superimposed

614 Sb fluid solubility contours of aqueous Sb species in hydrothermal fluids are from

615 Hagemann and Luders (2003).

616 Fig. 7. A schematic cartoon showing telescoped stibnite precipitation mechanisms steeply-

617 dipping and shallowly-dipping orebodies.

618
