13 **ABSTRACT**

14 Gold in Carlin-type gold ores is commonly hosted in the arsenian pyrite rim, but
15 the formation of arsenian pyrite and its contribution on Au adsorption are poorly
16 understood. Based on our previous NanoSIMS Au mapping, we conducted SEM and
17 HR-TEM analyses to examine the Au deportment and nano-scale texture of individual
18 auriferous arsenian pyrite grains from the giant Carlin-type Lannigou gold deposit in
19 SW China. The results indicate that the arsenian pyrite rim is composed of numerous
20 nanoparticulate pyrite grains (rather than a single crystal), and gold nanoparticles (Au^0)
21 occur mainly in sub-rim with the highest Au content, which are porous and lower
22 degree of order. We proposed that nanoparticulate arsenian pyrite attachment and
23 aggregation is the main mechanism for the arsenian pyrite rim growth, and such
24 mechanism is crucial for the Au efficient enrichment for this giant gold deposit.

28 INTRODUCTION

29 The Catlin-type gold deposits (CTGDs) are mainly found in Nevada (USA)
30 (Hofstra and Cline, 2000; Muntean and Cline, 2018) and SW China (Hu et al., 2002,
31 2017; Su et al., 2018). These deposits host the second largest Au resource on Earth
32 and provide over 9% of the global gold production (Cline et al., 2005; Muntean et al.,
33 2011; Large et al., 2011). Gold in unoxidized CTGDs is hosted exclusively in
34 hydrothermal arsenian pyrite, which usually contains thousands of ppm Au, three
35 orders of magnitude higher than that in typical ore fluid (<10 ppm) (Su et al., 2009;
36 Kusebauch et al., 2019). This implies an effective mechanism to concentration Au into
37 arsenian pyrite to form giant Au CTGDs.

38 Arsenian pyrite in CTGDs commonly precipitated around earlier gold-barren pyrite
39 cores, forming core-rim texture and/or small individual arsenian pyrite grains (Su et
40 al., 2018; Muntean et al., 2011; Cline, 2011). In addition, gold distribution in arsenian
41 pyrite rim shows micron-scale zoning, which was interpreted to be related to ore-fluid
42 geochemical changes during the pyrite rim growth (Barker et al., 2009; Yan et al.,
43 2018).

44 Previous works concluded that Au⁺ captured in pyrite rims is strongly affected by
45 the pyrite growth rate and mechanism (Fougerouse et al., 2019; Wu et al., 2019) and
46 surface electronegativity (Kusebauch et al., 2019; Rickard and Luther, 2007; Deditius
47 et al., 2014; Xian et al., 2019). Polycrystalline of arsenian pyrite were reported in
48 previous studies, and were interpreted to have formed by Au exsolution, rapid local
49 ore-fluid geochemical changes and/or temperature drop (Palenik et al., 2004; Deditius

50 [et al., 2008](#); [Wu et al., 2021](#)). However, the role of nanoparticulate pyrites and As-rich
51 pyrite-rim formation in Au efficient enrichment in CTGDs has not been well
52 understood.

53 Based on previous works on CTGDs in Nevada, we investigated the Au deportment
54 and nano-scale texture of individual auriferous arsenian pyrites from the giant
55 Carlin-type Lannigou gold deposit in SW China, via a combination of high-resolution
56 transmission electron microscopy (HR-TEM) and secondary electron microscopy
57 (SEM). We proposed that the attachment and aggregation of nanoparticulate arsenian
58 pyrites to form As-/Au-rich rim occur during the fluctuating disequilibrium
59 mineralization process.

60 **GEOLOGICAL BACKGROUND**

61 South China is composed of the Yangtze and Cathaysia blocks in the northwest and
62 southeast, respectively, and is bounded by the North China Craton and
63 Indochina-Simao Block to the north and southwest, respectively. The Youjiang Basin
64 is located in the southwestern Yangtze Block (Fig. 1), and is locally known as the
65 “Golden Triangle” due to the many Carlin-type gold deposits discovered since 1978
66 ([Tu, 1992](#)). The Youjiang Basin is composed of Neoproterozoic-Neoproterozoic
67 metamorphic rocks and Cambrian-Triassic carbonates and shales ([Hu et al., 2002](#);
68 [Peters et al., 2007](#); [Su et al., 2008](#); [Hu and Zhou, 2012](#); Fig. 1). Indosinian (Triassic)
69 to Yanshanian (Jurassic-Cretaceous) granitic plutons are present only on the margin of
70 the basin, although Triassic-Jurassic intrusions are inferred to be concealed beneath
71 the sedimentary strata according to inherited zircon data of mafic dikes ([Hu et al.,](#)

72 2002; Peters et al., 2007; Su et al., 2008; Hu and Zhou, 2012; Mao et al., 2013; Pi et
73 al., 2017; Zhu et al., 2017; Fig. 1).

74 The Lannigou (aka. Jinfeng) gold deposit is a giant CTGD in the Youjiang Basin
75 (Hu et al., 2002; Su et al., 2009, 2018; Fig. 1). The orebodies occur as veins and
76 lenses in the Middle Triassic Xuman and Bianyang formations calcareous siltstone
77 and mudstone, and are mainly controlled along steeply-dipping fault F3 (Yan et al.,
78 2018; Zhang et al., 2003; Fig. 2). The Dachang Formation was identified at depth of
79 Lannigou (Fig. 2A), which is widespread across the Youjiang Basin and has close
80 genetic link to the regional low-temperature mineralization (Liu et al., 2017). Previous
81 fluid inclusion studies on Lannigou suggested medium-low temperature (150-300°C)
82 and low-salinity (<6 wt.% NaCl_{eqv}) ore fluid with no occurrence of boiling (Zhang et
83 al., 2003; Yan et al., 2020). Major alteration styles include decarbonate, pyrite, silicic
84 and argillic alterations (Zhang et al., 2003; Fig. 3A). As one of the largest CTGDs in
85 China, the Lannigou deposit contains total Au reserve of over 109 tones (t) @ 3.83 g/t
86 (Su et al., 2018). Gold at Lannigou is invisible and hosted in arsenian pyrite, which is
87 the dominant sulfide in the auriferous quartz-sulfide veins (Su et al., 2009, 2018; Fig.
88 3A).

89 **SAMPLES AND METHODS**

90 **Sample descriptions**

91 Our samples were collected from a high-grade orebody (~7 g/t Au) at Lannigou.
92 The auriferous pyrites are closely related to silicification with typical core-rim texture
93 (Figs. 3A, B), as confirmed by micro-laser-Raman spectroscopy (Fig. 3C). Fractured

94 individual auriferous pyrites were prepared for SEM analyses to examine the
95 micro-nano structures in/between the core and rims. Polished thin sections were
96 prepared from these samples, which were mapped via the backscattered electron
97 (BSE), electron probe micro-analysis (EPMA) and nano-scale secondary ion mass
98 spectrometry (NanoSIMS) techniques (Yan et al., 2018) to select the FIB-TEM
99 analysis area. EPMA and BSE analyses were performed on a JEOL JSM7800F field
100 emission scanning electron microscope (FE-SEM). Nano-scale elemental mapping
101 was conducted on a CAMECA NanoSIMS 50L, with the effective ion beam depth of
102 < 100 nm (for S-isotope analysis) and < 10 nm (for elemental mapping) (McPhail and
103 Dowsett, 2009). Foil for TEM observation was conducted across a profile of the
104 selected area with ~10 μm depth (Fig. 4), and thus the NanoSIMS analysis has no
105 effect on the TEM observation. Detailed instrument conditions and procedures of
106 EPMA and NanoSIMS mapping were as described in previous studies (Yan et al.,
107 2018; Zhang et al., 2014, 2017).

108 Previous NanoSIMS mapping indicated that pyrite growth from Lannigou deposit
109 can be divided into three stages according to the Au-As contents (Yan et al., 2018;
110 Figs. 3D, E): Stage I As-Au-poor pyrite core is overgrown by stage II hydrothermal
111 pyrite rim (As-rich but Au-poor), which is in turn overgrown by stage III auriferous
112 arsenian pyrite rim. The stage III arsenian pyrite rim also can be divided into several
113 sub-rims and the 1st sub-rim is usually characterized by highest Au concentration.

114 **Micro-laser Raman spectroscopy**

115 To constrain the pyrite phase of the pyrite core and rim, we performed micro-Laser
116 Raman spectroscopic analysis using Renishaw RM 2000 and inVia Plus micro-Raman

117 spectrometers, equipped with a CCD detector at the Institute of Geochemistry,
118 Chinese Academy of Sciences. The laser (532 nm) energy is 50 mW, and the
119 acquisition time for each spectrum is 30 s. Silicon (520 cm^{-1} Raman shift) was used as
120 the standard.

121 **Scanning electron microscope (SEM) imaging**

122 The analysis was performed at the State Key Laboratory of Ore Deposit
123 Geochemistry (Guiyang), Chinese Academy of Sciences. Selected pyrite grains were
124 cracked to expose the fracture surface, and the fragments were placed on the copper
125 stump by conductive tapes and carbon coated. Secondary electron (SE) images were
126 collected with a JEOL JSM7800F SEM, under the operation conditions of 10 kV
127 accelerating voltage and 10 mm working distance.

128 **In situ lift-out TEM foil by Focused Ion Beam (FIB)**

129 Based on previous NanoSIMS Au mapping (Figs. 3D-E and 5A-B; [Yan et al., 2018](#)),
130 in-situ lift-out foils for TEM analysis from same pyrites were prepared with an FEI
131 Dual Beam Focused Ion Beam/Scanning Electron Microscope (FIB/SEM) system, at
132 the Center for Lunar and Planetary Sciences, Institute of Geochemistry, Chinese
133 Academy of Sciences (Fig. 4). Polished thin sections were carbon coated and the
134 selected areas were protected by platinum coating. The foils are about $15\ \mu\text{m} \times 7\ \mu\text{m}$
135 $\times 70\ \text{nm}$ in size. The areas with “curtain structures” on pyrite foils are usually caused
136 by the ion beam effect (Fig. 4D), which are avoided for the TEM analysis. The
137 vitrification of pyrite crystal may occur in the foils due to the ion beam affect, but this
138 lattice transformation can easily be observed and avoided under the bright field TEM.

139 Detailed analysis procedures follow those of Wirth (2009) (Figs. 4, 5), and are
140 summarized below:

141 (1) Positioning and Pt coating: the final thickness of the Pt layer is 2 μm , Ga^+ beam
142 current is 50 pA for real-time observation and 300 pA for Pt coating (30 kV).

143 (2) Initial digging for pyrite lamella: 15 nA for rough digging and 3nA for milling (30
144 kV), pyrite lamella thickness is $\sim 1 \mu\text{m}$ (Fig. 4A).

145 (3) Additional milling and partial cut of the pyrite lamella, 1 nA (30 kV).

146 (4) Final cut-off of pyrite lamella from the sample, 1 nA (30 kV).

147 (5) Lift out and attach to the copper grid with Pt coating, 50 pA (30 kV) (Figs. 4B-C).

148 (6) Final milling to $<100\text{nm}$ thickness pyrite foil, 1 nA, 500 pA and 300 pA (30 kV)
149 (Fig. 4D).

150 (7) Polishing of foil, 48 pA (5 kV) and 43 pA (2 kV).

151 **TEM observation**

152 Transmission electron microscopy (TEM) was conducted using an FEI field
153 emission (FE) gun microscope Tecnai G2 F20 S-TWIN with an energy dispersive
154 X-ray spectrometer (EDS), at the State Key Laboratory of Environmental
155 Geochemistry, Institute of Geochemistry, Chinese Academy of Science. Point-to-point
156 resolution is 0.24 nm, and can reach 0.19 nm in the STEM mode. The EDS detection
157 limit is ~ 1 w.t.% and the analysis area for single spot is about 40 nm in diameter. The
158 Fe-S-As peaks reflect the arsenian pyrite matrix, whilst Cu peak is mainly caused by
159 the Cu-grid.

160 **RESULTS**

161 **Gold deportment**

162 Typical of auriferous pyrite in CTGDs, oscillatory-zoned pyrite rim (hundreds of
163 nm wide) was also observed in foils by bright field TEM (BFTEM) and TEM-EDS
164 (Figs. 6A-B). Based on the positive correlation between band brightness (under
165 BFTEM) and As-Au contents, NanoSIMS Au mapping in horizontal plane of arsenian
166 pyrite (Yan et al., 2018; Figs. 5B, 6C) was used to indicate Au distribution in the
167 vertical arsenian pyrite foil for TEM (Fig. 6D). Two areas in stage III pyrite rim (with
168 different Au content) were selected to examine the quantity and occurrence of gold
169 nanoparticles.

170 Under BFTEM images, abundant Au nanoparticles (diameter: 10-40 nm) were
171 observed. Previous NanoSIMS study on the same sample has shown that the first
172 sub-rim has the highest Au content (No. 1 rim in Fig. 6C; Yan et al., 2018), and the Au
173 nanoparticles occur also mainly in this sub-rim (Fig. 6E). In contrast, there are only a
174 few Au nanoparticles in the other sub-rims, with slightly lower Au content (Fig. 6F).
175 Most of the observed gold nanoparticles is isolated from each other in pyrite rim
176 and/or closed to nanoparticulate pyrites which have different lattice fringes from Au
177 nanoparticles (Fig. 7A). A few of gold nanoparticles are distributed linearly within
178 nano-fractures in arsenian pyrite (Fig. 7B).

179 **Polycrystallinity of arsenian pyrite rim**

180 The micro-/nano-particulate pyrites were observed by secondary electron imaging
181 (SEI) of SEM in fractured individual auriferous pyrite (Fig. 8). Different from the
182 crystalline core with conchoidal fractures (orange circle in Fig. 8B), nanoparticulate
183 pyrites closed to the pyrite core show tetrahedron/irregular polyhedron shape or

184 spherule aggregates (diameter 100-500 nm) (Figs. 8B-D), whilst micro-particulate
185 pyrites in the outer shell (equal to arsenian pyrite rim) show typical pyritohedron
186 shape (diameter 10-30 μm) (Fig. 8E).

187 The selected area electron diffraction (SAED) and fast Fourier transformation (FFT)
188 pattern is the primary method to evaluate pyrite crystallization. The SAED or FFT
189 patterns of monocrystalline pyrite shows dot arrays. However, patterns of
190 polycrystalline pyrite show disorganized scatters (Deditius et al., 2008). Crystallinity
191 features of the stage II and III arsenian pyrite sub-rims were examined from the inner
192 to outer of pyrite rim by BFTEM image (Figs. 5C-E, 9B-E). Different from the SAED
193 feature of pyrite core (inset in Fig. 9A), SAED patterns of pyrite rim (insets in Figs.
194 9B-E) show disorderly feature with systematic change from inner to outer of arsenian
195 pyrite rim. Highly disorder (inset in Fig. 9D) and porous features were observed in
196 early-stage III pyrite sub-rim (equal to the 1st sub-rim of arsenian pyrite in Fig.6C),
197 which contains the highest Au content (Fig. 3E; Yan et al., 2018) and amount of Au
198 nanoparticles (Fig. 6E). Nanoparticulate pyritohedron pyrites (diameter: 10 nm (Fig.
199 7A) to 200 nm (Fig. 9F)) were observed under highly-magnified BFTEM. The
200 nanoparticulate pyrites have different lattice fringes, and the matrix between them is
201 composed of smaller nanoparticulate or colloidal pyrite grains (Fig. 7A).

202 **DISCUSSION**

203 **Gold department in arsenian pyrite**

204 Determining the invisible gold speciation and distribution in arsenian pyrite is
205 essential in understanding the Au deposition in CTGDs (Deditius et al., 2014;

206 [Pokrovski et al., 2019](#)). It is widely accepted that Au in the pyrite occurs as
207 structural-bound Au⁺ and minor submicron Au⁰ particles ([Muntean et al., 2011](#);
208 [Deditius et al., 2014](#); [Palenik et al., 2004](#); [Simon et al., 1999](#)). Based on the
209 decoupling between isolated distribution of gold nanoparticles and continuous
210 variation of Au concentration revealed by the high-resolution (100 nm) NanoSIMS Au
211 mapping ([Yan et al., 2018](#); Figs. 3E, 5B), we confirm that there is significantly more
212 structural-bound Au⁺ and/or Au⁰ atoms in the auriferous rim. Combining the absence
213 of fluid boiling in the Lannigou deposit and ore-fluid Au content of typical
214 Carlin-type gold deposits in SW China (<10 ppm) ([Zhang et al., 2003](#); [Su et al., 2009](#);
215 [Su et al., 2009](#); [Yan et al., 2020](#)), we suggest that Au was mainly absorbed from
216 Au-undersaturated fluid as ionic state and/or atom clusters, rather than deposited as
217 nanoparticles from Au-supersaturated fluid.

218 Gold nanoparticles could be formed by multiple mechanisms: Previous
219 experimental studies suggested that as Au-HS complexes were adsorbed onto the
220 pyrite surface. Some S⁻² ions in the complexes may be oxidized to S⁻¹, and form more
221 pyrite and reduce Au⁺ to Au⁰ ([Kusebauch et al., 2019](#); [Scaini et al., 1998](#)). Exsolution
222 of Au⁰ in arsenian pyrite could be caused by Au oversaturation as solid solution state
223 in pyrite ([Palenik et al., 2004](#); [Reich et al., 2005](#); [Deditius et al., 2014](#)). Gold
224 atom-scale clusters could also be generated by slower pyrite crystal growth
225 ([Fougerouse et al., 2016](#)). Temperature rise or recrystallization of metastable arsenian
226 pyrite would also trigger Au nanoparticle formation, as Au⁰-Au⁰ bonds are more

227 energetically favorable than bonds between Au⁰ and pyrite matrix (Becker et al., 2001;
228 Mikhlin et al., 2006).

229 In our samples, the isolated Au nanoparticles (Fig. 7A) could be formed by
230 accumulation of reduced Au atoms/clusters during the arsenian pyrite rim formation.
231 In contrast, the linear distributed Au nanoparticles (Fig. 7B) were likely formed by
232 later exsolution and accumulation, possibly led by temperature rise and/or auriferous
233 pyrite recrystallization. Compared with the Au-poor area (Fig. 6F), there are more Au
234 nanoparticles in 1st sub-rim of stage III, which has the highest Au content (Fig. 6E).

235 **Growth of arsenian pyrite rim and Au adsorption**

236 Gold-rich arsenian pyrite is commonly formed through the reaction of Au-HS
237 complexes (e.g., Au(HS)⁰, Au(HS)₂⁻) in the As⁻/H₂S⁻ bearing fluid with reactive iron in
238 Fe-bearing carbonate minerals and occupies the vacancy of dissolved carbonate in the
239 wall-rock (Hofstra and Cline, 2000; Muntean and Cline, 2018; Su et al., 2009;
240 Kusebauch et al., 2019). Previous works revealed the occurrence of nanoparticulate
241 pyrites in arsenian pyrites, which were interpreted as the phase transition of
242 metastable arsenian pyrite, caused possibly by Au exsolution or rapid pyrite
243 precipitation (Palenik et al., 2004; Deditius et al., 2008; Wu et al., 2021).

244 In our SEI and TEM analyses, the quantity and shapes of nanoparticulate pyrites in
245 arsenian pyrite rim (Figs. 7A, 8-9) suggest that these nanoparticulate pyrites were
246 formed from rapid disequilibrium precipitation, instead of phase transition of
247 metastable arsenian pyrites. The different directions of nanoparticulate pyrites' lattice
248 fringe under TEM analyses and (Fig. 7A) and multiple shapes (Fig. 8D) of

249 nanoparticulate pyrites under SEM observation suggest that the pyrite rim grew by
250 attachment and aggregation, rather than by single crystal or epitaxial growing (Wu et
251 al., 2021). The highly disorder and porous feature of pyrite rims in early stage III (Fig.
252 9D) could be generated by a more fluctuating fluid conditions, and formed the first
253 sub-rim with the highest Au concentration (No. 1 sub-rim; Fig. 6C). Previous in-situ
254 NanoSIMS S-isotope and As/Au mapping supported such fluctuating fluid conditions
255 (Yan et al., 2018; Figs. 3E, 5C). The occurrence of nanoparticulate (~10 nm) and
256 colloidal (<10 nm) pyrites (Fig. 7A) suggested that the observed nano-scale zoning
257 (Figs. 6A-B) may also be caused by fluid fluctuation or diffusion-limited
258 self-organization process (Wu et al., 2019).

259 Previous studies suggested that, under such fluctuating fluid conditions, FeS₂ could
260 be supersaturated and nucleation rate of pyrite is likely much higher than growth rate,
261 and amount of pyrite nuclei were formed (Wu et al., 2021; Hu et al., 2019). Benefit
262 from the nano-scale size and the Brownian movement, these pyrite nuclei may not
263 have precipitated immediately from the fluid, but keep growing into nanoparticulate
264 pyrite (Banfield et al., 2000). Due to crystallographic parameters preference (Tan et
265 al., 2015), these nanoparticulate pyrites would preferentially attach and aggregate
266 onto the surface of pre-existing pyrite, forming the core-rim texture observed (Fig. 3),
267 as well as some auriferous arsenian pyrite clusters (Figs. 5A-B). The micro-particulate
268 pyrites (Fig. 8E) could be formed by recrystallization of nanoparticulate pyrites which
269 is similar to the transformation process from pyrite framboids to euhedral pyrite
270 (Sawlowicz, 1993).

271 Gold adsorption could be affected by many factors. Experimental studies have
272 demonstrated that Au can be efficiently chemisorbed by arsenian pyrite as $\text{Au}(\text{HS})^0$
273 and $\text{Au}(\text{HS})_2^-$ complexes (Fleet et al., 1997; Widler and Seward, 2002; Palenik et al.,
274 2004; Xing et al., 2019). Previous studies showed that incorporation of arsenic and
275 complex crystal shape could decrease the surface electronegativity of pyrite and
276 promote Au-HS chemisorption (Deditius et al., 2008, 2014; Kusebauch et al., 2019;
277 Xian et al., 2019). Compared with monocrystalline pyrite (diameter $\sim 100 \mu\text{m}$), the
278 surface area of pyrite nanoparticles (diameter $\sim 10 \text{ nm}$) is tens of thousand times higher
279 (Langmuir, 1916) and more beneficial for Au chemisorption. The porosity of arsenic
280 pyrite rim (Figs. 9D, F) could allow continuous chemisorption of Au by the
281 precipitated nanoparticulate pyrites until they are solidified and isolated from the ore
282 fluid.

283 **IMPLICATIONS**

284 **Pyrite growth model for Au efficient enrichment**

285 Gold nanoparticles and nanoparticulate pyrites were revealed by FIB-TEM at the
286 stage II and III of auriferous pyrite rim in the giant Lannigou gold deposit, SW China.
287 Based on our results, published studies of arsenian pyrite and aggregation-based
288 crystal growth model of natural iron oxyhydroxide (Banfield et al., 2000), we
289 proposed that auriferous pyrite growth based on attachment and aggregation is
290 essential for Au enrichment in this giant CTGD, as explained below in detail (Fig.
291 10).

292 1. High-As and low-Au pyrite rim composed by nanoparticulate arsenian pyrites

293 was formed (Figs. 10A-B) by the initial high-As and low-Au fluid pulse and pH
294 buffer effect caused by fluid-rock interaction, in which substantial H₂S is consumed to
295 produce the H⁺ needed [H₂S → H⁺ + HS⁻] for Fe-bearing carbonate dissolution
296 [Ca(Fe)CO₃ + 2H⁺ → Ca(Fe)²⁺ + H₂O + CO₂], which is a key factor for pyrite
297 formation in CTGDs (Cline et al., 2005; Muntean et al., 2018; Hu et al., 2002).
298 Increased HS⁻ would hamper Au chemisorption via Fe(S, As)₂ + Au(HS)₂⁻ → Fe(S,
299 As)₂ · Au(HS)⁰ + HS⁻ (Simon et al., 1999; Bowers, 1991).

300 2. Alternatively, with more high-As-Au ore fluid recharge and extensive
301 neutralization of acidic ore fluid, the arsenian nanoparticulate pyrites would adsorb
302 substantial amount of Au from the ore fluid, even though the fluid was
303 Au-undersaturated (Fig. 10B). Meanwhile, these auriferous arsenian nanoparticulate
304 pyrites attached on the earlier-formed low-Au pyrite would form high-Au arsenian
305 pyrite rims (Fig. 10C).

306 3. Due to temperature dropping and recrystallization of nanoparticulate pyrite,
307 native gold nanoparticles were formed by exsolution and accumulation of
308 structural-bound Au⁰ grains and aggregates (Fig. 10D).

309 **Economic geology implications**

310 Pyrite is the most common sulfide in hydrothermal gold deposits, including
311 orogenic, porphyry, epithermal and volcanic-hosted massive sulfide (VHMS) types.
312 The ubiquitous zoning in pyrite from these deposits suggests that the ore fluids have
313 undergone fluctuation and disequilibrium processes (Cline et al., 2005; Deditius et al.,
314 2011, 2014; Goldfarb et al., 2005; Large et al., 2007, 2009; Reich et al., 2013; Sung et

315 [al., 2009; Thomas et al., 2011](#)). In epithermal and VHMS deposits, colloform and
316 nanoscale pyrites occur widely in growth or sector zoning of pyrite, with high
317 concentrations of Au, As and Cu ([Deditius et al., 2008, 2009; Barrie et al., 2009;](#)
318 [Masslennikov et al., 2009](#)). This suggests that nanoparticulate pyrite precipitation may
319 be common and important for Au efficient enrichment in these hydrothermal gold
320 deposits.

321 In addition, the occurrence of nano-gold may also have an impact on the Au
322 recovery in refractory ores from these gold deposits. Currently, refractory gold ores
323 are oxidized firstly for Au chemical leach ([La Brooy et al., 1994; Eldorado Gold Corp.](#)
324 [Ltd., 2011](#)). A better understanding of the forming mechanism of nano-gold, including
325 redox process of Au^+ and temperature behavior of Au^0 , may lead to more
326 cost-effective methods for Au recovery.

327 **ACKNOWLEDGEMENTS**

328 We thank staffs from the Jinfeng Mine Ltd. for their field support, and Dr. Bing Mo
329 for the sample preparation. This research was jointly funded by National Natural
330 Science Foundation of China (U1812402, 41830432, 41903044) and the China
331 Postdoctoral Science Foundation (2018M643531).

500 **Figure captions**

501 **Fig. 1** Regional geology of the Youjiang Basin, showing the location of Lannigou Au
502 deposit (modified after [Su et al., 2018](#)).

503 **Fig. 2** Geological map (A) and profile (B) of the Lannigou gold deposit (after [Yan et](#)
504 [al., 2020](#)).

505 **Fig. 3** Core-rim texture of auriferous pyrite revealed by reflected-light, BSE and
506 NanoSIMS: A, B: Reflected-light photos showing the auriferous pyrite coexists with
507 quartz and clay minerals; C: micro laser-Raman spectra of pyrite core and rim,
508 compared with standard pyrite. Standard pyrite data are from the RRUFF project
509 database (<https://rruff.info>). Raman shift peaks of core and rim mimic those of
510 standard pyrite at 341 cm^{-1} and 375 cm^{-1} ; D, E: BSE and NanoSIMS Au maps of
511 selected pyrite, showing the three pyrite growth stages (after [Yan et al., 2018](#)).

512 **Fig. 4** Schematic diagram showing the procedure of in-situ lift-out TEM foils
513 prepared by focused ion beam (FIB) technique: A: initial digging; B: lifting out; C:
514 attachment to the copper grid using Pt deposition; D: final milling to $<100\text{ nm}$
515 thickness and polishing. White box in D shows the “curtain” structure caused by FIB
516 ion beam effect.

517 **Fig. 5** Locations of the TEM foils shown in Figures 6, 7, 9: White boxes denote the
518 TEM foil profile locations. A, B: BSE and NanoSIMS Au maps of selected pyrite
519 shown in Figures 6-7. C: BSE image of selected pyrite shown in Figure 9. Red dots
520 show NanoSIMS $\delta^{34}\text{S}$ values, and orange dots show EPMA arsenic content (data from
521 [Yan et al., 2018](#)). D, E: TEM foils shown in Figure 9.

522 **Fig. 6** Occurrence of gold nanoparticles. A, B: Arsenic oscillatory zoning revealed by

523 bright field TEM image. C: NanoSIMS Au map to indicate Au content for TEM
524 observation in B. Line a-b denotes the TEM foil profile location. Numbers 1-5
525 represents the 1st to 5th Au-rich sub-rims, and the color legend is as in Figure 5. D:
526 bright field TEM image of the foil. E, F: Gold nanoparticles in bright field TEM
527 image of the Au-rich sub-rims (E) and Au-poor part (F).

528 **Fig. 7** Separated and linear distributed gold nanoparticles. A: HRTEM image of a
529 gold nanoparticle and nano-phase pyrites with different lattice fringes; B: bright field
530 TEM image showing linear distribution of gold nanoparticles; C, D: Representative
531 TEM-EDS of pyrite matrix and gold nanoparticles. Nano-Au = Au nanoparticles. Py
532 NPs= pyrite nanoparticles.

533 **Fig. 8** Nano-phase pyrites from fractured auriferous pyrite: A: SEI image of the
534 cracked pyrite grain. The majority of this grain is gold-barren core with bits of stage II
535 pyrite rim; B, C: magnified SEI image of selected area; D: Nano-pores and
536 nanoparticulate pyrites (distinct from broken pyrite fragments in Figure 8B) with
537 irregular or spherical shape; E: microparticulate pyrites in stripy stage II and III pyrite
538 rim.

539 **Fig. 9** Nano-phase pyrites revealed by FIB-TEM. A-E: bright field TEM images
540 showing the core and inner to outer rim, and their respective SAED patterns are
541 shown in the insets. White-dashed circles in A-E shown the SAED locations; F: bright
542 field TEM image of nanoparticulate arsenian pyrites (50-100 nm diameter)
543 (white-dashed polygon). Nano-Py = nanoparticulate pyrite.

544 **Fig. 10** Schematic diagram for the auriferous arsenian pyrite rims growth and Au

545 adsorption. Black dots and spots denote the dissolved Au (Au^+ and Au^0) and Au
546 nanoparticles, respectively.
