21 **ABSTRACT**

22 Uranotungstite is an uranyl-tungstate mineral that was until recently only partially characterized
23 with a formula originally given as $(\text{Fe}^{2+}, \text{Ba}, \text{Pb})(\text{UO}_2)_2(\text{WO}_4)(\text{OH})_4 \cdot 12\text{H}_2\text{O}$ and an unknown
24 crystal structure. This mineral has been reinvestigated by electron microprobe analysis coupled
25 with 3D electron diffraction. According to the electron microprobe data, the holotype material
26 from the Menzenschwand uranium deposit (Black Forest, Germany) has the empirical formula
27 $(\text{Ba}_{0.35}\text{Pb}_{0.27})_{\Sigma 0.62}[(\text{U}^{6+}\text{O}_2)_2(\text{W}^{6+}_{0.98}\text{Fe}^{3+}_{0.26}\square_{0.75})\text{O}_{4.7}(\text{OH})_{2.5}(\text{H}_2\text{O})_{1.75}](\text{H}_2\text{O})_{1.67}$ (average of 8 points

§ Email: plasil@fzu.cz

28 calculated on the basis of 2 U *apfu*; the H₂O content derived from the structure). According to the
29 precession-assisted 3D ED data, holotype uranotungstite from Menzenschwand is monoclinic,
30 $P2_1/m$, with $a = 6.318(5) \text{ \AA}$, $b = 7.388(9) \text{ \AA}$, $c = 13.71(4) \text{ \AA}$, $\beta = 99.04(13)^\circ$ and $V = 632(2) \text{ \AA}^3$ (Z
31 $= 2$). The structure refinement of the 3D ED data using the dynamical approach ($R_{obs} = 0.0846$ for
32 3287 independent observed reflections) provided a structure model composed of
33 heteropolyhedral sheets. A β -U₃O₈-type sheet of idealized composition
34 $[(UO_2)_2W^{6+}Fe_{0.25}^{3+}\square_{0.75}O_{4.75}(OH)_{1.5}(H_2O)_{1.75}]^{0.25-}$ is composed of UO₇ polyhedra linked by
35 (W,Fe)O₅ polyhedra in which the W:Fe ratio is variable as well as the bulk occupancy of this site;
36 the W site may also host a minor proportion of Cu, Mg, or V. In uranotungstite, the interlayer
37 spaces between adjacent U-W-O sheets host water on one side and, on the other side, a partially
38 occupied cation site mostly occupied by Ba and, to a lesser extent, Pb, as well as a partially
39 occupied H₂O site. This work is the first structural description of a natural uranyl-tungstate
40 mineral and confirms the great structural and chemical flexibility of β -U₃O₈ type of sheets.

44

45

INTRODUCTION

46 Uranotungstite is the only uranyl tungstate known in nature and is a scarce alteration product
47 of oxidation-hydration weathering of uraninite. Its rarity mostly arises from a rather unusual
48 association of uranium and tungsten in the most common types of uranium deposits worldwide. It
49 was described for the first time by Walenta (1985) from the Menzenschwand (also referred to as
50 Krunkelbach) uranium deposit in the Black Forest, Baden-Württemberg, Germany. The type

51 material forms spherulitic aggregates of 0.3 mm in diameter and is associated with meta-
52 uranocircite, meta-heinrichite, and other secondary uranium minerals. Apart from the commonly
53 observed yellow, brown-yellow to orange colors, the mineral may also be olive-green, greenish,
54 or blackish. Electron microprobe analysis (EMPA) of the type material led to the reported
55 empirical formula $(\text{Fe}_{0.38}\text{Ba}_{0.37}\text{Pb}_{0.36})_{\Sigma 1.11}\text{U}_{1.82}\text{W}_{0.99}\text{H}_{28.94}\text{O}_{24}$, where Fe was considered divalent.
56 This formula was then idealized to $(\text{Fe, Ba, Pb})(\text{UO}_2)_2(\text{WO}_4)(\text{OH})_4 \cdot 12\text{H}_2\text{O}$ by Walenta (1985).
57 Later on, more uranotungstite was found by Walenta (1985) from the Clara barite-fluorite mine in
58 the Black Forest, Germany, but in the Clara mine material, only traces of Ba and no Pb were
59 semiquantitatively detected.

60 Based on the morphology of the lath-like crystals of the type material, the mineral was first
61 assumed to be orthorhombic and the unit-cell parameters $a = 9.22$, $b = 13.81$, $c = 7.17 \text{ \AA}$ ($Z = 2$)
62 were proposed on the basis of a tentatively indexed X-ray powder diffraction pattern. The lath-
63 like crystals show (010) as a flattening plane and they exhibit perfect cleavage. Unlike the type
64 material from Menzenschwand, the Clara mine samples rather show thin platy, subparallel
65 crystals with a diamond-shaped outline. Nevertheless, the crystal structure of the type material
66 could not be determined by X-ray diffraction (powder or single crystal) due to the very small size
67 and subparallel intergrowth of the crystals. More generally, except for its original description, the
68 mineral has remained poorly studied; the crystal structure was still unknown before our present
69 study and there is not much available information about the crystal chemistry and the paragenetic
70 position in the weathering process. Furthermore, some aspects of the original description
71 appeared to be doubtful: (i) the presence of Fe^{2+} in a mineral formed under oxidizing conditions;
72 (ii) the co-assignment of Fe, Ba, and Pb in the chemical formula. We point out that previous
73 studies show that Fe^{3+} and W^{6+} replace each other in the crystal structures of oxide minerals

74 because of their very similar ionic radii (Kolitsch 1998; Atencio et al. 2010). Moreover, as
75 demonstrated by microchemical tests of a Clara mine sample using the reagents Merckoquant
76 10.004 (Fa. Merck) and KSCN, the iron in the mineral is trivalent, not divalent as it was
77 suggested in the early studies. Among the large cations, either Ba^{2+} , Pb^{2+} , K^+ , or Bi^{3+} may be
78 dominant (the latter two are not present in the type material) and minor or trace contents of Cu
79 are very common. In some samples associated with lenoblite, $V_2^{4+}O_4 \cdot 2H_2O$, notable amounts of
80 V, up to ~4 at. %, were found, as well as trace amounts of Mg. Another example of the chemical
81 variety existing in uranotungstite is illustrated by an uranotungstite sample from Les Montmins,
82 Allier, France, for which Cuchet et al. (2000) reported Pb, U, W, and Fe as well as trace amounts
83 of Ba, P, Cu, and As.

84 All the above-mentioned facts motivated us to reinvestigate uranotungstite from the type
85 locality (Menzenschwand) by EMPA and the entire suite of uranotungstite-like phases from
86 elsewhere. The attempted structural study of specimens from Menzenschwand was severely
87 hampered by the fact that uranotungstite does not form crystals large enough to be used by
88 conventional X-ray diffraction methods. Nevertheless, in the light of the recent success and
89 developments of 3D electron diffraction techniques (3D ED) (Gemmi and Lanza 2019; Gemmi et
90 al. 2019) such a study is now possible and was undertaken on uranotungstite from the type
91 locality. Here we present the first crystal-structure determination of this unique natural uranyl
92 tungstate mineral.

93

94

SPECIMENS AND OCCURRENCES

95 The two samples used in this study originate from the Menzenschwand uranium deposit, Black
96 Forest (Schwarzwald), Germany, which is the type locality for uranotungstite (Walenta 1985).

97 We used the holotype specimen of uranotungstite deposited in the collection of the Staatliches
98 Museum für Naturkunde in Stuttgart (Germany). Due to a minimal volume available for the
99 analysis, the sample from the holotype specimen was prepared for the polished-section mount
100 directly in the museum and used for subsequent EMPA (sample 1). The holotype specimen
101 consists of a quartz-barite gangue with disseminated to massive supergene uranyl minerals.
102 Besides uranotungstite, they comprise uranocircite/metauranocircite and most probably meta-
103 heinrichite, mentioned in the original description. Visual inspection suggests that there are at
104 least two types of tabular crystals belonging probably to different minerals of the so-called
105 uranium micas. Uranotungstite forms small orange spherules, consisting of fine tabular crystals;
106 these spherules reach up to 0.3–0.4 mm across.

107 Additionally, a rich specimen of uranotungstite from Menzenschwand obtained via Carsten
108 Slotta (Minttreasure.com, Hausach, Germany) has been used for the 3D ED characterization
109 (sample 2) (Fig. 1). Uranotungstite forms globular to massive aggregates of orange color in vugs
110 of a quartz gangue with relics of uraninite (scarce). Along with rare uranotungstite, the vugs host
111 uranophane, studtite, phosphuranylite, billietite, and ubiquitous hematite. Surprisingly, later on,
112 during the transmission electron microscopy experiments, it was found that the orange crystalline
113 aggregates studied consist of uranotungstite, but the prevailing phase is francevillite, which has
114 not been reported from Menzenschwand so far.

115 Apart from the specimens mentioned above, we also investigated several uranotungstite-like
116 phases from the Clara mine (Germany) and the Medvědí uranium deposit (Czech Republic), but
117 only the latter will be addressed here.

118

119

CHEMICAL COMPOSITION

120 The chemical composition of the very small sample extracted from the holotype specimen
121 (sample 1) was determined quantitatively using a Cameca SX100 electron microprobe operating
122 in wavelength-dispersive mode (WDS) and operated with an accelerating voltage of 15 kV, a
123 beam current of 4 nA, and a 5 μm beam diameter. All samples were stable under the beam. The
124 following X-ray lines and standards and lines were used: Ca $K\alpha$ (wollastonite), K $K\alpha$ (sanidine),
125 Fe $K\alpha$ (andradite), W $L\alpha$ (ZnWO_4), Ba $L\beta$ (BaSO_4), Pb $M\alpha$ (vanadinite), and U $M\alpha$ (parsonsite).
126 The elements F, Na, Mg, Al, Si, P, S, Cl, Ti, V, As, Se, Sr, and Bi were also sought, but their
127 contents were below the respective detection limits. The peak counting times were 10–20 s, and
128 the counting time for each background point was 50% of the time for the peak. The measured
129 intensities were converted to elemental concentrations using the PAP program (Pouchou and
130 Pichoir 1985). The type material from Menzenschwand (Table 1) has the following empirical
131 formula (average of eight points, calculations based upon 2 U atoms per formula unit, *apfu*):
132 $(\text{Ba}_{0.35}\text{Pb}_{0.27})_{\Sigma 0.62}[(\text{U}^{6+}\text{O}_2)_2(\text{W}^{6+}_{0.98}\text{Fe}^{3+}_{0.26}\square_{0.75})\text{O}_{4.7}(\text{OH})_{2.5}(\text{H}_2\text{O})_{1.75}](\text{H}_2\text{O})_{1.67}$ (the proportions of
133 O and OH were obtained from the stoichiometry derived from the structure refinement, see
134 section Discussion for details). The cation stoichiometry of this formula is, except for H and O
135 associated with OH/ H_2O , reasonably close to the one determined by Walenta (1985),
136 $(\text{Fe}_{0.38}\text{Ba}_{0.37}\text{Pb}_{0.36})_{\Sigma 1.11}\text{U}_{1.82}\text{W}_{0.99}\text{H}_{28.94}\text{O}_{24}$.

137 The chemical composition of the uranotungstite used for the structure determination was
138 determined only semiquantitatively using an EDS detector coupled to the transmission electron
139 microscope used for precession electron diffraction tomography. The semiquantitative elemental
140 ratios obtained from the EDS spectra (Fig. 2) are Ba:Pb \sim 80:20 and W:Fe \sim 53:47.

141

142

3D ELECTRON DIFFRACTION AND STRUCTURE DETERMINATION

143 *3D ED data collection*

144 Transmission electron microscopy (TEM) has been chosen for the structural characterization of
145 uranotungstite due to the limited amount of available material, the minute size of uranotungstite
146 crystals, and the concomitant presence of francevillite (Fig. 3). A few pieces of the mineral were
147 scratched from the Menzenschwand sample 2 and gently crushed in ethanol. A drop of the
148 uranotungstite-containing ethanol was then deposited on a Cu-grid covered with a thin film of
149 holey amorphous carbon. To preserve the hydrated nature of uranotungstite under the high TEM
150 vacuum, the cryo-plunging conditions were used to transfer the sample in the TEM: the grid was
151 plunged into liquid nitrogen and then transferred to an FEI Tecnai 02 TEM (acceleration voltage
152 of 200 kV, LaB₆) using a Gatan cryo-transfer holder and equipped with a side-mounted CCD
153 camera Olympus Veleta with a 14-bit dynamic range. This method, initially used for organic and
154 biological samples, was recently applied to hydrated inorganic samples (Mugnaioli et al. 2020;
155 Steciuk et al. 2019, 2021) and is now used routinely in our group to analyze new minerals by 3D
156 ED. Nowadays, single-crystal electron diffraction data can be collected using one of the 3D ED
157 techniques that are extensively described in Gemmi and Lanza (2019) and Gemmi and Mugnaioli
158 (2019). In this study, the precession-assisted electron diffraction tomography (PEDT) method
159 was used (Vincent and Midgley 1994; Kolb et al. 2007, 2008; Mugnaioli et al. 2009) wherein the
160 precession of the electron beam aims to reduce the dynamic effects. The precession angle of the
161 beam was kept at 1° during the experiment using the precession device Nanomegas Digistar.
162 Finding a good candidate to collect 3D ED data on uranotungstite was a challenging task as the
163 majority of crystals barely diffract. A lower crystallinity of the supergene minerals, to which
164 uranotungstite belongs, is commonly observed, and diffraction data often suffer from disorder
165 features and low resolution (Steciuk et al. 2020). Small diffracting crystal fragments were

166 fortunately found at the nanoscale, partially covered by francevillite (Fig. 3), from which PEDT
167 data could be recorded at 100 K. For each selected crystal area, a series of non-oriented patterns
168 are sequentially collected by step of 1° on the accessible tilt range of the goniometer automated
169 by the in-house software, including the tracking of the crystal following the procedure described
170 by Plana-Ruiz et al. (2020) and Kolb et al. (2019). The data reduction was performed using the
171 computer programs PETS2 (Palatinus et al. 2019).

172

173 *Data processing and structure solution*

174 Based on two merged data sets, uranotungstite is monoclinic, $a = 6.318(5) \text{ \AA}$, $b = 7.388(9) \text{ \AA}$, $c =$
175 $13.71(4) \text{ \AA}$, $\beta = 99.04(13)^\circ$ and $V = 632(2) \text{ \AA}^3$. The reciprocal-space sections are consistent with
176 the space group $P2_1/m$ (with the extinction condition $k = 2n$ for $0k0$ reflections) (Fig. 3). This unit
177 cell and space group provide very satisfactory indexing of the X-ray powder diffraction pattern
178 reported by Walenta (1985). New features in PETS2 allow a better data reduction of 3D ED data
179 by optimizing the orientation and the scale of each frame and fitting the intensity profile for the
180 integration (for detailed information, check Palatinus et al. 2019). This procedure leads to two
181 *hkl*-type files: one for the structure solution and the kinematical refinement (where the two data
182 sets are combined), and another file (one for each data set) dedicated to the dynamical refinement
183 where each ED frame is considered independent (Palatinus et al. 2015a, b). The completeness
184 reached 83.6% for a $\sin\theta/\lambda = 0.7 \text{ \AA}^{-1}$ resolution shell (Tab. 4). The structure was solved with the
185 Superflip program (Palatinus and Chapuis 2007; Palatinus 2013) and refined from 3D ED data
186 using Jana2020 (Petříček et al. 2014).

187 The initial structure model showed a layered structure where the electrostatic potential map
188 defined a rather sharp and fully occupied uranyl- MO_5 layer ($M = W^{6+}$ and Fe^{3+}) and two types of

189 interlayers: one containing a partially occupied Ba/Pb position surrounded by water molecules,
190 and another one with a water molecule only. The single *M* site is shared by W^{VI} and Fe^{III}. To
191 stabilize the refinement of the partially occupied Ba/Pb site, the Ba:Pb ratio was set to 80:20
192 according to the ratio obtained by energy-dispersive spectroscopy (EDS) coupled to the TEM.
193 The EDS analysis also shows a Fe:W ratio around 53:47 but this value is possibly inaccurate and
194 the proper ratio is better determined from the refinement of the fully occupied Fe/W site.
195 Restraints were applied in the refinement of 3D ED data because the lack of coverage along *c* is
196 responsible for a lower accuracy of the *z/c* coordinates. The bond distances among the U sites and
197 the apical oxygen atoms constituting the UO₂²⁺ ion were restrained to a value of 1.800(2) Å
198 (Evans 1963; Burns et al. 1997a; Lussier et al. 2016). Additionally, a soft restraint of 1.920(3) Å
199 was applied to the bond length between W1 and its apical oxygen ligand (O5). Moreover, the
200 overall occupancy of Ba and Pb must, at least, compensate for the additional negative charge
201 occurring when Fe³⁺ substitutes W⁶⁺ and was thus restricted accordingly (conformation C in Fig.
202 4). Note that the free refinement gives a slightly lower value for the cumulative occupancy of Ba
203 and Pb, showing that the conformation labeled B in Figure 4 is improbable in the two studied
204 crystal fragments. Two hydrogen positions around O3 were weakly revealed by the difference
205 potential map after few refinement steps (Palatinus et al. 2017). The small proportion of
206 hydrogen linked to O5 (H₂O) when Fe is located in the octahedrally coordinated site is not visible
207 from our data. The O–H distances were restrained to 1.000(2) Å with the isotropic displacement
208 parameters of the hydrogen atoms set as riding with an extension factor of 1.5. The final
209 refinement converged to $R_{\text{obs}}/wR_{\text{obs}} = 0.0846/0.0589$ for 3287 independent observed reflections,
210 with $I > 3\sigma(I)$. With a refined occupancy of W_{1.20(1)}Fe_{0.80(1)} the structural formula is
211 (Ba_{0.32}Pb_{0.08})_{Σ0.40}[(U⁶⁺O₂)₂W⁶⁺_{1.2}Fe³⁺_{0.8}O_{7.2}(H₂O)_{3.2}] for *Z* = 2. The complete CIF file, also

212 containing a block with the full reflection data, is deposited as Supplemental material. Selected
213 interatomic distances are reported in Table 2, the full bond-valence analysis (following general
214 rules given by Brown 1981, 2002, and using bond-valence parameters from Gagné and
215 Hawthorne 2015) is provided as Supplementary Table S1.

216

217 DESCRIPTION OF THE STRUCTURE

218 The structure of uranotungstite contains fifteen independent atom sites (non-hydrogen) in the
219 asymmetric unit. There are two unique U sites; one unique mixed (W,Fe) site; one partially
220 occupied, interlayer (Ba,Pb) mixed site, and eleven O sites of which two (labeled O3 and O10)
221 correspond to interlayer H₂O/OH groups (Fig. 4). The U sites are coordinated by seven O atoms;
222 two of them (further designated as O_{Ur}) represent strongly bonded atoms in the UO₂²⁺ ion at a
223 distance of ~1.8 Å from the central U atom (Evans 1963; Burns et al. 1997a; Lussier et al. 2016).
224 The other five atoms of the UO₇ polyhedra are localized at the horizontal apices of the pentagonal
225 bipyramid. The mixed (W,Fe) site is coordinated by five ligands up to 2 Å in the form of a
226 tetragonal pyramid. The (Ba,Pb) site is coordinated to eight ligands (up to 3 Å), including two
227 O_{Ur} atoms (O6 and O8), the apical O atom of the (W,Fe)-polyhedra (symmetrically related O5),
228 and H₂O groups (O10 in the (010) plane) (Tables 2, S1).

229 The UO₇ polyhedra share edges to form infinite chains of polyhedra extending along [010]
230 that are interconnected *via* (W,Fe)O₅ polyhedra (Fig. 5). The uranyl-anion topology of the
231 uranotungstite sheet is shown in Fig. 4b. This sheet is built from pentagons, squares, and
232 triangles; pentagons and squares are centered by U^{VI} and (W,Fe), while the centers of triangles
233 are not occupied in uranotungstite. The sheet topologically belongs to that of the β-U₃O₈ type,
234 which is characterized by the sequence ...DRU... (Fig. 5c) (Miller et al. 1996; Burns 2005).

235 Additionally, apart from the structure of β - U_3O_8 (Loopstra 1970), such a sheet was also found in
236 the structures of ianthinite (Burns et al. 1997), billietite (Finch et al. 2006), spriggite (Brugger et
237 al. 2006), rameauite (Plášil et al. 2016), shinkolobweite (Olds et al. 2017), and nollmotzite (Plášil
238 et al. 2018). The stacking of the U-(W,Fe)-O sheets parallel to (001) is based on the alternation of
239 U-(W,Fe)-O sheets of 3.94 Å thickness with, on one side, a layer occupied only by water
240 molecules (O3) (layer thickness 2.14 Å) and, on the other side, a layer containing a (Ba,Pb) site
241 and an H_2O (O10) molecule with a layer thickness of 3.49 Å (Fig. 6). In this way, the unit cell
242 has a general stacking sequence built from four layers: U-(W,Fe)-O sheet | $\text{H}_2\text{O}/\text{OH}$ | U-(W,Fe)-
243 O sheet | (Ba,Pb)- H_2O . The layered character of the uranotungstite structure explains the perfect
244 cleavage of the mineral parallel to (001) and its platy crystal habit.

245

246

DISCUSSION

247 *The chemical formula of uranotungstite*

248 The chemical formula of uranotungstite is interesting in many ways as all the reported
249 analyzed specimens of uranotungstite exhibit a wide compositional diversity. This is evident in
250 the type material found in the Menzenschwand deposit with a high amount of W Pb, Ba, and Fe,
251 to specimens with only traces of Pb and Ba from the Clara mine and others, containing additional
252 traces of several other elements like V, Mg, or Cu. Another example comes from the
253 aforementioned uranotungstite from Les Montmins in France that is Pb-dominant, with only
254 traces of Ba, Cu, P, and As (Cuchet et al. 2000). From 3D ED data collected at the nanoscale
255 from Menzenschwand sample 2, the (W,Fe) site $(\text{W}_{1.2}\text{Fe}_{0.8})_{\Sigma 2}$ appears fully occupied, unlike what
256 is shown by the EPMA data (sample 1) at a larger scale with $(\text{W}_{0.98}\text{Fe}_{0.26})_{\Sigma 1.24}$. In uranotungstite,
257 the cationic disorder and the vacancies in the Ba/Pb and W/Fe sites offer four theoretically

258 possible local conformations labeled A, B, C, and D where the amount of water molecules and/or
259 hydroxyl groups is variable (Fig. 4); in the following discussion, x is the number of OH+H₂O
260 visible in the refined model, and n is the theoretical number of additional water molecules in the
261 interlayer. While those conformations are only representing local ordering schemes and end-
262 members, they allow a better understanding of the significant chemical variability observed
263 between the two studied samples first, and, to a larger extent, in uranotungstite samples from
264 different localities. The two theoretical conformations A and D are defined as the two end-
265 members with formulas (UO₂)₂W₂O₈(H₂O)₂ and (UO₂)₂(OH)₄(H₂O)₆. They are considered as
266 end-members as they both exhibit an empty interlayer in the absence of (Ba, Pb) and its
267 associated H₂O (O10). In conformation B, the presence of Ba and W gives a formula
268 (Ba,Pb)(UO₂)₂W₂O₈(OH)₂(H₂O) that promotes a hydroxyl group allowing three H₂O/OH ($x = 3$).
269 On the other hand, the presence of Fe^{III} in the W/Fe (conformation C) site brings three additional
270 negative charges, and the concomitant presence of Ba/Pb is a necessary condition to enable
271 charge neutrality, leading to an ideal hypothetical W-free composition of
272 (Ba,Pb)(UO₂)₂Fe₂O₆(H₂O)₅ ($x = 5$). In conformations B and C the stacking of the layers is
273 stabilized by covalent and strong hydrogen bonds and there is no obvious spare space to host
274 additional interlayer water molecules (n) (Fig. 4a). However, from our structural model, in the
275 two end-members A ($x = 2$) and D ($x = 10$), the stacking of the U-W/Fe layers is ensured by
276 strong hydrogen bonds on one side whereas, on the other side, the empty interlayer (Ba,Pb,H₂O)
277 has to be filled by additional interlayer H₂O molecules to allow the layers to be connected. In
278 theory, for each conformation A and D (for $Z = 2$), the interlayer can host at least $n = 2$ additional
279 H₂O (Fig. 4b). Results of the 3D ED data show 60% and 40% of the conformations A and C,
280 respectively. The refinement shows clearly that the B conformation is not significantly present as

281 the amount of (Ba,Pb), when freely refined, barely compensates the negative charge brought by
282 the presence of Fe^{III} (conformation C) on the (W,Fe) site and was later restricted to ensure charge
283 balance. It means that there is not enough (Ba,Pb) to allow conformation B to occur in the two
284 crystals used for the structural analysis. On the other hand, the EMPA data of sample 1, which
285 were measured at a larger scale, document the presence of 49% of conformation B, 13% of C,
286 and 38% of D (Fig. 4). Therefore, two uranotungstite compositions are determined: EMPA of
287 sample 1 gives a formula $(\text{Ba}_{0.35}\text{Pb}_{0.27})_{\Sigma 0.62}[(\text{U}^{\text{VI}}\text{O}_2)_2(\text{W}^{\text{VI}}_{0.98}\text{Fe}^{\text{III}}_{0.26}\square_{0.75})\text{O}_{4.7}(\text{OH})_{2.5}(\text{H}_2\text{O})_{1.75}]-$
288 $(\text{H}_2\text{O})_{1.67}$, whereas 3D ED and TEM-EDS of sample 2, distinctly poorer in Pb, but richer in Fe,
289 leads to $(\text{Ba}_{0.32}\text{Pb}_{0.08})_{\Sigma 0.40}[(\text{U}^{\text{VI}}\text{O}_2)_2\text{W}^{\text{VI}}_{1.2}\text{Fe}^{\text{III}}_{0.8}\text{O}_{7.2}(\text{H}_2\text{O})_{1.75}](\text{H}_2\text{O})_{1.45}$. Considering the possible
290 additional water molecules allowed by the conformations A and D, the 3D ED model contains
291 from $x = 3.2$ to $x + n \approx 4.4$ water molecules while the EMPA data correspond to a range from $x =$
292 5.9 to $x + n \approx 6.7$ molecules.

293 Using the same structural model, the compositions differ by their proportions of Ba/Pb and
294 W/Fe as well as for the bulk occupancies of these two cationic sites. However, Ba and W always
295 remain dominant over Pb and Fe, and no other elements are detected. In that regard, the cation
296 proportions are in line with the compositional characteristics of the type material. The difference
297 between the formula derived by EPMA and the refinement of 3D ED data is easily explained by
298 the possible local variation of the samples' compositions. Our 3D ED study is based on the two
299 best-crystallized areas found during the experiment and might not represent uranotungstite's bulk
300 composition. It demonstrates that the structure of uranotungstite allows and is characterized by a
301 significant chemical variability. Because the EPMA data are more representative of the bulk
302 composition, the ideal formula of uranotungstite is set accordingly as
303 $(\text{Ba}_{0.35}\text{Pb}_{0.27})_{\Sigma 0.62}[(\text{U}^{\text{VI}}\text{O}_2)_2(\text{W}^{\text{VI}}_{0.99}\text{Fe}^{\text{III}}_{0.26}\square_{0.75})\text{O}_{4.75}(\text{OH})_{1.5}(\text{H}_2\text{O})_{1.75}](\text{H}_2\text{O})_{1.67}$. From this formula,

304 the ideal composition of the U-W/Fe-O sheet shown in Fig. 6 becomes
305 $[(\text{UO}_2)_2(\text{WFe}_{0.25}\square_{0.75})\text{O}_{4.75}(\text{OH})_{1.5}(\text{H}_2\text{O})_{1.75}]^{0.25-}$, with two interlayers $[(\text{Ba}_{0.354}\text{Pb}_{0.271})_{\Sigma 0.625-}$
306 $(\text{H}_2\text{O})_{0.625}]^{1.25+}$ and $[(\text{H}_2\text{O})(\text{OH})]^-$.

307 The chemical formula obtained from the results of the crystal-structure refinement and EPMA
308 is not consistent with the formula given by Walenta (1985) in the original description. First, it is
309 unambiguous that Fe^{III} partially occupies the W^{VI} site and does not exist as isolated cations in the
310 interlayer space; only $\text{Ba}^{2+}/\text{Pb}^{2+}$ cations and H_2O molecules are localized there. Furthermore, it is
311 clear that the simplified formula given by Walenta (1985),
312 $(\text{Fe}^{\text{II}},\text{Ba},\text{Pb})(\text{UO}_2)_2(\text{WO}_4)(\text{OH})_4 \cdot 12\text{H}_2\text{O}$, as well as the current IMA-accepted formula,
313 $\text{Fe}(\text{UO}_2)_2(\text{WO}_4)(\text{OH})_4 \cdot 12\text{H}_2\text{O}$, both differ from the presently obtained formula, namely in the
314 overall H_2O content (considered as $\text{H}_2\text{O} + \text{OH}$). While these formulae contain 14 H_2O in total,
315 our results indicate a much lower content, up to about 6 H_2O molecules per formula unit ($\text{OH} +$
316 H_2O). Adding the theoretical n H_2O to the formula brings the number up to 7, still far from the 14
317 H_2O of Walenta (1985). The H_2O content given by Walenta (1985) was determined by
318 calculations of the weight loss after heating a sample up to 350 °C, however, without any details
319 given. According to Walenta (1985), the electron microprobe analyses were then recalculated,
320 including the corresponding weight (in wt. %) of H_2O obtained from the heating. Since there are
321 no details in the paper by Walenta (1985) we cannot exclude that the sample was contaminated
322 and we should consider these results with caution.

323 The newly undertaken chemical analysis of uranotungstite holotype material nonetheless
324 documented that the cation content of the formula given initially by Walenta (1985) is not so far
325 from that determined here. The redetermined composition of the holotype uranotungstite from
326 Menzenschwand by EPMA, $(\text{Ba}_{0.35}\text{Pb}_{0.27})_{\Sigma 0.62}[(\text{U}^{\text{VI}}\text{O}_2)_2(\text{W}^{\text{VI}}_{0.99}\text{Fe}^{\text{III}}_{0.26}\square_{0.75})\text{O}_{4.75}(\text{OH})_{1.5-}$

327 $(\text{H}_2\text{O})_{1.75}](\text{H}_2\text{O})_{1.67}$ (H_2O from the stoichiometry derived by the structure determination),
328 demonstrates that it is Ba-dominant, with some variations in the Ba:Pb ratio. The studied
329 aggregates from the type specimen contain neither K nor Bi. The IMA formula, which considers
330 the mineral as Fe^{2+} -dominant, should therefore be revised entirely.

331 **IMPLICATIONS**

332 In contrast to schoepite-related minerals and phases formed during the initial stages of
333 uraninite alteration, uranotungstite belongs to the group of supergene phases derived from the
334 long-term alteration of uraninite, similarly to, e.g., the uranyl-oxide mineral uranosphaerite,
335 $\text{Bi}(\text{UO}_2)\text{O}_2(\text{OH})$ (Hughes et al. 2003; Plášil 2018; Colmenero et al. 2020). Those uranyl-oxide
336 minerals that belong to the long-term alteration products are characteristic concerning their high
337 molar proportion of incorporated metal elements by comparison to the content of molecular H_2O
338 in their crystal structures (Finch and Ewing 1992; Plášil 2018). These metal elements are usually
339 released from the gradually weathering uraninite (such as radiogenic Pb) and host rocks (Na, K,
340 Ca). In the case of uranotungstite, the molar proportion of metal cations to molecular H_2O is
341 0.31:0.43 (from crystal-structure data) and the molar *Me*:U ratio is 0.31:0.26, thus matching the
342 region of “relic” phases (*cf.* Plášil 2018).

343 Among others, we have investigated “uranotungstite” specimens from the Medvědíň uranium
344 deposit that enabled a more detailed look at the mineral association at the micro-scale. A
345 uranotungstite-like mineral (containing Bi dominating over Pb) from Medvědíň belongs
346 undoubtedly to the “relic” phases. This conclusion is supported by the mineral assemblage (Fig.
347 7a) comprising uranophane- α (forming pseudomorphs after pitchblende and tiny veins), tabular
348 crystals of saléeite and torbernite, and their relics, U-bearing to U-rich bismutoferrite, and,

349 additionally, the Bi-dominant uranotungstite-like mineral. The latter forms relatively compact
350 aggregates, to 10 μm across, embedded in the relics of torbernite and saléeite (Fig. 7b).

351 The high chemical variability and potentially close structural relationship of a large number of
352 related Ba/Pb/Fe/W/Bi-substituted "uranotungstite-like" structures, which remain unclear at the
353 moment, prompted further research into the mineralogy of weathered U(Bi/W)-deposits. We are
354 convinced that such research can be important due to implications for nuclear waste management
355 as Bi was a very common element used during the production of Pu since the 1940s.

356 ACKNOWLEDGMENTS

357 Comments by Travis Olds, an anonymous reviewer, and the structure editor helped us to
358 significantly improve the manuscript. We are indebted to Stephan Wolfsried (Stuttgart,
359 Germany), Carsten Slotta (Hausach, Germany), Dietmar Schrenk (Hornberg, Germany), Richard
360 Bayerl (Stuttgart, Germany), and Heinz Förch (Sindelfingen, Germany) for providing us with
361 samples for study. This work was financially supported by the Czech Science Foundation (GACR
362 20-11949S), by OP VVV project (Geobarr CZ.02.1.01/0.0/0.0/16_026/0008459 to RS), and the
363 fieldwork at the Medvědíň hill has been allowed by the Administration of the Krkonoše
364 Mountains National Park.

519 Table 1. Chemical composition (in wt.% oxides, from EPMA) of the holotype specimen of
 520 uranotungstite from Menzenschwand.

Constituent	Mean	Range	Stand. Dev.	Standard
PbO	5.49	5.30–5.80	0.19	vanadinite
BaO	4.76	4.54–5.02	0.15	baryte
FeO	1.67	1.55–1.73	0.06	andradite
WO ₃	20.65	19.87–22.04	0.72	syn. ZnWO ₄
UO ₃	51.35	50.63–53.65	1.07	parsonsite
Total	83.96			

521

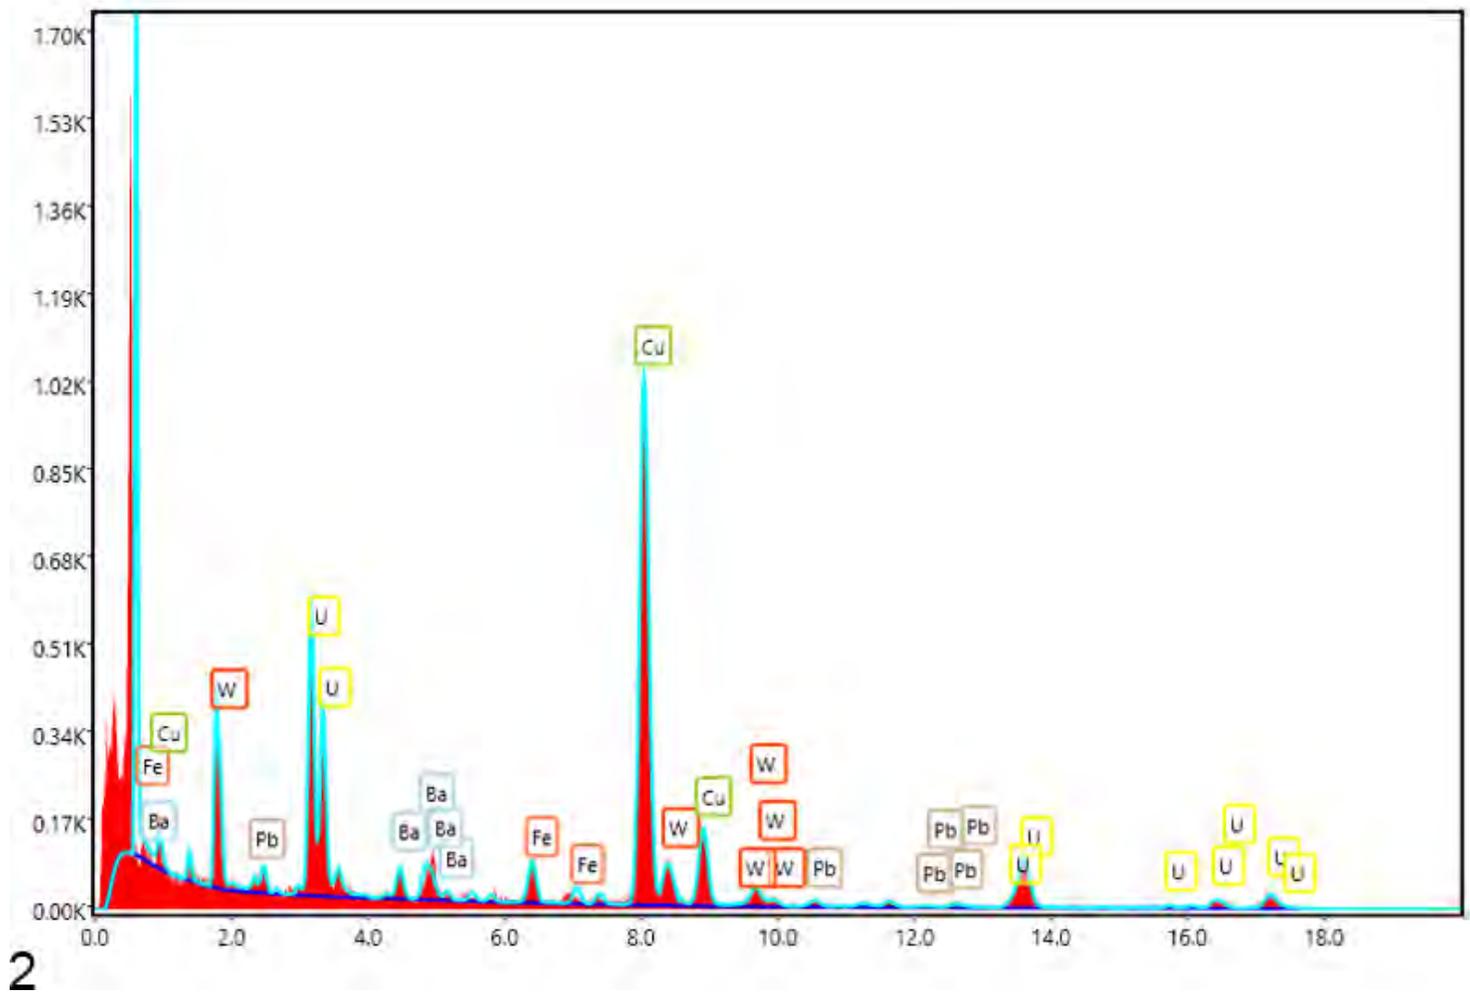

522 Table 2. Selected bond distances (Å) for uranotungstite.

U–O		W1/Fe1–O		O–H	
U1–O2	1.797(12)	W1/Fe1–O3	2.25(2)	O3–H1O3	1.00(2)
U1–O7	2.404(7)	W1/Fe1–O4	1.898(5)	O3–H2O3	0.997(17)
U1–O7	2.404(7)	W1/Fe1–O5	1.894(13)		
U1–O8	1.793(12)	W1/Fe1–O7	1.919(7)	H···O (H···A)	
U1–O9	2.287(6)	W1/Fe1–O9	1.875(6)	H1O3···O1	1.96(2)
U1–O9	2.287(6)	W1/Fe1–O11	1.910(5)	H2O3···O2	1.947(16)
U1–O11	2.387(9)				
		Ba1/Pb1–O			
U2–O1	1.802(12)	Ba1/Pb1–O5	2.711(13)		
U2–O4	2.446(9)	Ba1/Pb1–O5	2.735 (13)		
U2–O6	1.790(12)	Ba1/Pb1–O5	2.735(13)		
U2–O7	2.197(6)	Ba1/Pb1–O5	2.711(13)		
U2–O7	2.197(6)	Ba1/Pb1–O6	2.856(15)		
U2–O9	2.343(7)	Ba1/Pb1–O8	2.862(15)		
U2–O9	2.343(7)	Ba1/Pb1–O10	2.60(2)		
		Ba1/Pb1–O10	2.60(2)
