Abstract

9 We focus on the ferric end-member of phase H: ϵ -FeOOH using density functional theory at the
10 PBEsol+U level. At 300 K, we find that ϵ -FeOOH undergoes a hydrogen bond symmetrization at
11 37 GPa and a sharp high-spin to low-spin transition at 45 GPa. We find excellent agreement with
12 experimental measurements of equation of state, lattice parameters, atomic positions, vibrational
13 frequencies, and optical properties as related to the band gap, which we find to be finite and
14 small, decreasing with pressure. The hydrogen bond symmetrization transition is neither first-,
15 nor second-order, with no discontinuity in volume or any of the elastic moduli. Computed IR and
16 Raman frequencies and intensities show that vibrational spectroscopy may provide the best
17 opportunity for locating the hydrogen bond symmetrization transition experimentally. We find
18 that ϵ -FeOOH is highly anisotropic in both longitudinal- and shear-wave velocities at all
19 pressures, with the shear wave velocity varying with propagation and polarization direction by as
20 much as 24% at zero pressure and 43% at 46 GPa. The shear and bulk elastic moduli increase by
21 18% across the high-spin to low-spin transition.

22

23

Introduction

24 Water is an important component in the mantle, which even in small concentrations can have a
25 large effect on properties such as the melting temperature and viscosity, and thus on thermal
26 evolution. The amount of water stored in the largest part of the mantle, the lower mantle, is still
27 uncertain. This is partly due to the relative inaccessibility of this region, for example few
28 physical samples from the lower mantle are known, in contrast to the increasing number of
29 diamond inclusions and other samples from the transition zone (Pearson et al. 2014; Tschauer et
30 al. 2018). Our uncertainty about the water content in the lower mantle is also due to a
31 comparative lack of understanding of hydrogen bonding at high pressure: in what phases is water
32 crystallographically stored, and what is the effect of water on physical properties at high
33 pressure?

34

35 Water storage may be fundamentally different in the lower mantle than in the transition zone. In
36 the transition zone, copious amounts of water may be stored in nominally anhydrous minerals,
37 including wadsleyite and ringwoodite, which have water storage capacities exceeding 1 wt. %
38 (Hirschmann 2006). In the lower mantle, however, the water storage capacity of the major
39 phases (bridgmanite, ferropericalse, davemaoite), while still uncertain, appears not to exceed
40 1200 ppm (Litasov and Ohtani 2007; Fu et al. 2019; Chen et al. 2020; Liu et al. 2021). If the
41 lower mantle has a water concentration much higher than this, the water must be stored in
42 hydrous phases, i.e. phases in which water is a stoichiometric component.

43

44 Phase H is the hydrous phase that is found to be stable in mantle-like whole rock compositions
45 with excess H₂O (Walter et al. 2015) over most of the lower mantle pressure regime (55-125
46 GPa). These experiments were limited in not containing iron oxide as a component, but other

47 studies have found stable solid solution of phase H encompassing essentially the entire ternary
48 (Mg,Fe,Al)(Si,Fe,Al)(OOH)₂ (Nishi et al. 2019), complementing studies of binary joins in this
49 compositional space (Ohira et al. 2019, 2021; Satta et al. 2021).

50

51 Our focus here is on the ferric end-member of phase H: ϵ -FeOOH. ϵ -FeOOH has an
52 orthorhombic structure with $P2_1nm$ space group that is stable on its own composition from 7 GPa
53 (where it transforms from the lower pressure, goethite phase) to 70 GPa, where it transforms to a
54 pyrite-structured phase (Gleason et al. 2008; Nishi et al. 2017; Suzuki 2017; Hu and Liu 2021).
55 The structure is an orthorhombically distorted rutile derivative with edge- and corner-sharing
56 FeO₆ octahedra linked by hydrogen bonds (O-H \cdots O) that are asymmetric at low pressure (Pernet
57 et al. 1975; Bolotina et al. 2008). The anhydrous sub-lattice (arrangement of Fe and O atoms) is
58 identical to the CaCl₂ high-pressure polymorph of stishovite.

59

60 Under pressure ϵ -FeOOH displays rich behavior undergoing two transitions: hydrogen bond
61 symmetrization and a high-spin to low-spin transition. The ϵ -FeOOH phase thus serves as a
62 model system for studying two transitions that are thought to be important in many mantle
63 phases at high pressure. Hydrogen bond symmetrization occurs in a variety of materials at high
64 pressure, including phase H (Tsuchiya and Mookherjee 2015), phase D (Tsuchiya et al. 2005),
65 and H₂O (Holzapfel 1972; Aoki et al. 1996; Meier et al. 2018). The high-spin to low-spin
66 transition occurs in a wide variety of ferrous and ferric oxides and silicates (Lin et al. 2005;
67 Tsuchiya et al. 2006; Gleason et al. 2008; Badro 2014; Liu et al. 2014; Holmström and Stixrude
68 2015). A unique feature of ϵ -FeOOH is that the two transitions (hydrogen bond symmetrization
69 and high-spin to low-spin transition) are thought to occur at similar pressures, and the nature of

70 possible interaction between these two transitions, i.e. whether one drives the other, is still
71 uncertain (Gleason et al. 2013; Xu et al. 2013; Thompson et al. 2020).
72
73 Hydrogen bond symmetrization occurs as the O-O distance of O-H...O decreases, while the O-H
74 bond length increases, leading to a linear symmetric O-H-O configuration and promotion of the
75 space group symmetry to *Pnmm*. The symmetrization transition has been widely studied in the
76 Al-end member of phase H (δ -AlOOH) (Tsuchiya et al. 2008; Tsuchiya and Tsuchiya 2009;
77 Sano-Furukawa et al. 2018) and has been predicted to occur in the MgSi- end-member (Tsuchiya
78 and Mookherjee 2015; Solomatova et al. 2022). The pressure at which symmetrization occurs in
79 ϵ -FeOOH is uncertain as neutron diffraction studies have not yet been performed on this phase at
80 high pressure, and previous theoretical studies focused on the symmetrically bonded structure
81 (Thompson et al. 2017).

82
83 The high-spin to low-spin transition occurs as increasing crystal field splitting on compression
84 causes d-electrons in the e_g manifold to pair up with those in the t_{2g} manifold, yielding a change
85 in the magnetic moment of the Fe^{3+} cation from $5\mu_B$ to $1\mu_B$, and a collapse in volume. The high-
86 spin to low-spin transition has been found to occur between 40 and 60 GPa in experimental
87 studies (Gleason et al. 2013; Xu et al. 2013; Thompson et al. 2020). The high-spin to low-spin
88 transition in ϵ -FeOOH has not yet been studied theoretically; part of the reason is that transition
89 metal oxides present a challenge to conventional density functional theory, which tends to
90 underestimate the strong correlation among the d electrons.

91

92 Here we explore the behavior of ϵ -FeOOH at high pressure with density functional theory
93 augmented by local electron repulsion that captures the strong correlation (DFT+U). We study
94 both transitions (hydrogen bond symmetrization and high-spin to low-spin) and explore the
95 changes in properties that occur across them. We focus on physical properties that have been
96 previously measured experimentally in this system, including the structure, equation of state, and
97 vibrational frequencies, and on those that may be relevant to geophysical detection of phase H in
98 the lower mantle, including elasticity, and electronic properties.

99

100

Methods

101 Our calculations are based on density functional theory (DFT), using the projector augmented
102 wave (PAW) method (Kresse and Joubert 1999) as implemented in the Vienna ab initio
103 Simulation Package (VASP) (Kresse and Furthmüller 1996). We use the PBEsol generalized
104 gradient approximation (Perdew et al. 2008), which we have previously shown to yield excellent
105 agreement with experiment in iron-bearing oxides (Holmström and Stixrude 2015). To account
106 for strong correlation, we use the +U method (Anisimov et al. 1997). On the basis of our
107 calculations of the dependence of the spin transition pressure and optical properties on U-J, our
108 previous results for the value of U-J for divalent iron (Holmström and Stixrude 2015), and
109 expected trends with respect to iron valence state (Mosey et al. 2008), we settled on a value of U-
110 J = 3.2 eV. We use PAW potentials of 14, 1, and 6 valence electrons for Fe, H, and O with core
111 radii of 1.16, 0.37, and 0.82, respectively. We perform spin-polarized simulations where the
112 difference in the number of up-spin and down-spin electrons on each Fe atom is set to the high-
113 spin (5) or low-spin (1) value for both anti-ferromagnetic and ferromagnetic arrangements (Fig.
114 1a and Fig. 1b). We also explored a mixed-spin arrangement in which half of the Fe are high-

115 spin and the other half are low-spin (Fig. 1c). We found that sampling the Brillouin zone using a
116 $4 \times 4 \times 4$ k-point mesh and a basis-set energy cutoff of 1000 eV was sufficient to converge
117 energy and pressure to within 3 meV/atom and 0.1 GPa, respectively. For calculation of the
118 electronic density of states we use the tetrahedron method (Blochl et al. 1994) and a $20 \times 20 \times 20$
119 k-point mesh. For phonon calculations, we use a $2 \times 2 \times 2$ supercell and a $2 \times 2 \times 2$ k-point mesh.
120

121 We calculate the elastic constants by applying finite strains ε_{kl} to the lattice and computing the
122 resultant stresses σ_{ij} , yielding the components of the elastic constant tensor as $\sigma_{ij} = c_{ijkl}\varepsilon_{kl}$.
123 We choose a strain magnitude of 0.005 and strains (in Voigt notation): $\varepsilon_1, \varepsilon_2, \varepsilon_3$, and $\varepsilon_4 + \varepsilon_5 +$
124 ε_6 appropriate for the orthorhombic case (Le Page and Saxe 2002). The isotropic bulk and shear
125 moduli are determined using the Voigt-Reuss-Hill (Hill 1952) measure. We compute single
126 crystal elastic wave velocities via the Christoffel equation $|c_{ijkl}\mathbf{n}_j\mathbf{n}_l - \rho v^2\delta_{ik}| = 0$ where c_{ijkl}
127 is the single-crystal elastic tensor, \mathbf{n} is the propagation direction, ρ is the density, v is the
128 velocity, and δ_{ik} is the Kronecker delta (Musgrave 1970). The eigenvalues yield the elastic wave
129 velocities, and eigenvectors the polarization directions. We fit our theoretical results to the
130 Eulerian finite strain expansion (Stixrude and Lithgow-Bertelloni 2005):

131

$$c_{ijkl} = (1 + 2f)^{\frac{5}{2}} \left\{ c_{ijkl0} + (3K_0c'_{ijkl0} - 5c_{ijkl0})f \right. \\ \left. + \left[6K_0c'_{ijkl0} - 14c_{ijkl0} - \frac{3}{2}K_0\delta_{kl}^{ij}(3K'_0 - 16) \right] f^2 \right\}$$

132

(1)

133 where $f = \frac{1}{2} \left[\left(\frac{V}{V_0} \right)^{-2/3} - 1 \right]$, c_{ijkl} is the elastic tensor, the subscript 0 refers to the reference state

134 ($P = 0$ GPa, $T_0 = 300$ K), and $\delta_{kl}^{ij} = -\delta_{ij}\delta_{kl} - \delta_{il}\delta_{jk} - \delta_{jl}\delta_{ik}$.

135

136 We calculate the phonon vibrational frequencies via density functional perturbation theory
 137 (DFPT) (Gajdoš et al. 2006). Phonon frequencies and eigenvectors are computed in the harmonic
 138 limit from the second-order force constant matrix $\Phi_{\alpha\beta}(jl, j'l')$, the elements of which are the
 139 change in the force in the α Cartesian direction acting on atom j in unit cell l , in response to the
 140 displacement of atom j' in unit cell l' in the β direction (Wilson et al. 1980). The phonon
 141 frequencies are the eigenvalues of the dynamical matrix at a given wavevector \mathbf{q} :

142

143
$$D_{\alpha\beta}^{jj'}(\mathbf{q}) = \frac{1}{\sqrt{m_j m_{j'}}} \sum_{l,l'} \Phi_{\alpha\beta}(jl, j'l') \exp[i\mathbf{q} \cdot (\mathbf{r}(j', l') - \mathbf{r}(j, l))] \quad (2)$$

144 where m_j are the atomic masses and l and l' are the unit cells of the two atoms.

145

146 The long-ranged Coulomb interactions lead to non-analytic corrections in the limit $\mathbf{q} \rightarrow 0$, that
 147 cause splitting of longitudinal optic (LO) and transverse optic (TO) modes (Pick et al. 1970;
 148 Gonze and Lee 1997):

149

150
$$D_{\alpha\beta}^{jj'}(q \rightarrow 0) = D_{\alpha\beta}^{jj'}(q = 0) + \frac{1}{\sqrt{m_j m_{j'}}} \frac{4\pi}{\Omega_0} \frac{[\sum_{\gamma} q_{\gamma} z_{\gamma\alpha}^j][\sum_{\gamma'} q_{\gamma'} z_{\gamma'\beta}^{j'}]}{\sum_{\alpha\beta} q_{\alpha} \epsilon_{\alpha\beta}^{\infty} q_{\beta}} \quad (3)$$

151

152 where $Z_{\alpha\beta}^j$ is the Born effective tensor, ε^∞ is the macroscopic dielectric tensor, and Ω_0 is the
153 volume of the cell.

154

155 We compute infrared (IR) intensities from the eigen-displacements around the gamma-point,
156 where the atom's change in polarizability with respect to atomic displacement is captured by the
157 Born effective-charge tensors (Giannozzi and Baroni 1994):

158

$$159 \quad I_{IR}(s) = \sum_{\alpha} \left| \sum_{j\beta} Z_{\alpha\beta}^j \frac{w(s,j)}{\sqrt{m_j}} \right|^2 \quad (4)$$

160

161 where $\mathbf{W}(s,j)$ is the eigenvector of the dynamical matrix corresponding to mode s .

162

163 We compute Raman intensities from the change in the polarizability tensor α along the mode
164 eigenvectors in terms of the macroscopic high-frequency dielectric constant (Skelton et al. 2017),
165 via a central finite-difference scheme:

166

$$I_{Raman}(s) \propto \frac{\partial \alpha}{\partial Q(s)} \equiv \frac{\partial \varepsilon^\infty}{\partial Q(s)} \approx \frac{\Delta \varepsilon^\infty}{\Delta Q(s)}$$

167

$$I_{Raman,\alpha\beta}(s) = \frac{\Omega}{4\pi} \left[-\frac{1}{2} \frac{\varepsilon_{\alpha\beta}^\infty(-s)}{\Delta Q(s)} + \frac{1}{2} \frac{\varepsilon_{\alpha\beta}^\infty(+s)}{\Delta Q(s)} \right]$$

168

(5)

169 where Q is the normal-mode coordinate at the Γ -point and is defined by $\mathbf{u}(s, j) = Q(s) \frac{\mathbf{W}(s, j)}{\sqrt{m_j}}$,

170 where $\mathbf{u}(s, j)$ is the atomic displacement. The unpolarized Raman intensity takes the form:

171

$$I_{Raman} = 45 \left[\frac{1}{3} (I_{xx} + I_{yy} + I_{zz}) \right]^2 + \frac{7}{2} [(I_{xx} - I_{yy})^2 + (I_{xx} - I_{zz})^2 + (I_{yy} - I_{zz})^2 + 6(I_{xy}^2 + I_{xz}^2 + I_{yz}^2)]$$

172 (6)

173

174 To compute phonon frequencies and IR and Raman intensities, we use Phonopy and Phonopy-
175 Spectroscopy (Togo and Tanaka 2015; Skelton et al. 2017).

176

177 We find the pressure of the high-spin to low-spin transition as the point at which the Gibbs free
178 energies of the two phases are equal:

179

$$G(P, T) = H(P, static) + F_{TH}(V, T) + P(V, T)V,$$

180 (7)

181

182 where H is the enthalpy at static (athermal) conditions, G is the Gibbs free energy as a function
183 of pressure P and temperature T , V is the volume, and F_{TH} is the Helmholtz free energy derived
184 from the (quasi-)harmonic phonon energy. The pressure

185

$$P(V, T) = P(V, static) + P_{TH}(V, T)$$

186 (8)

187

188 where $P_{TH} = -\left(\frac{\partial F_{TH}}{\partial V}\right)_T$ and

189

190
$$F_{TH} = \frac{1}{2} \sum_{qj} \hbar \omega_{qj} + k_B T \sum_{qj} \ln[1 - \exp(-\frac{\hbar \omega_{qj}}{k_B T})] \quad (9)$$

191

192 where ω is the phonon frequency. We have found that the thermal free energy of the
193 asymmetrically bonded phase is nearly independent of volume, yielding essentially zero thermal
194 pressure. This result is inconsistent with experimental measurements of positive thermal
195 expansivity (Suzuki 2016), indicating that anharmonicity, which is not included at our level of
196 theory, is important in the asymmetric phase. We hypothesize that the thermal free energy of the
197 asymmetric phase can be approximated by that of the symmetric phase at the same volume. Our
198 hypothesis could be tested by performing molecular dynamics simulations, which are beyond the
199 scope of this study because of the much greater computational cost.

200

201

Results

202 At static conditions, we find that the ground state is high-spin anti-ferromagnetic (AFM), in
203 agreement with a neutron diffraction study at ambient pressure (Pernet et al. 1975) (Fig. 2). The
204 AFM state is more stable than the ferromagnetic (FM) state by 0.5 eV per unit cell (0.25 eV
205 /formula unit) at zero pressure and 0.8 eV at 40 GPa. At 40 GPa, the lowest energy state
206 becomes low-spin AFM. In the low-spin state, AFM is more stable than FM by 0.02 eV at 40
207 GPa, to 0.01 eV at 100 GPa. We also find that the mixed-spin state is less stable than the high-

208 spin state at 40 GPa by 0.4 eV. Because AFM is the most stable, all subsequent results refer to
209 the AFM arrangement.

210

211 We find hydrogen bond symmetrization to occur within the stability field of the high-spin state
212 (Fig. 3). The transition occurs at a static pressure of 34 GPa. The symmetrization transition
213 occurs without discontinuity in structure or volume and is therefore not first order. We also show
214 results for the (metastable) symmetrization transition in the low spin state, which occurs at a
215 static pressure of 5 GPa.

216

217 We find excellent agreement with experimental measurements of the equation of state of the
218 high-spin and low-spin states and the pressure of the high-spin to low-spin transition (Suzuki
219 2010, 2016; Gleason et al. 2013; Ikeda et al. 2019; Thompson et al. 2020) (Fig. 4). We find that
220 the high-spin to low-spin transition occurs at 45 GPa at 300 K. We find disagreement with some
221 previous experiments, including those of Gleason et al. (2013), at pressures greater than 50 GPa,
222 which may be due to the lack of a pressure medium in this experiment, resulting in deviatoric
223 stress and systematic overestimation of volumes (Meng et al. 1993). The symmetrization
224 transition has only a subtle effect on the equation of state: the symmetric and asymmetric
225 equations of state are nearly coincident within the symmetric high spin stability field and there is
226 no discontinuity in volume at the symmetrization transition. At 300 K, the symmetrization
227 transition occurs at 37 GPa. All subsequent results are referred to the pressure at 300 K.

228

229 Our computed crystal structures agree well with ambient structure determinations and with high
230 pressure measurements of the lattice parameters (Fig. 5, Table 1). We find a change in relative

231 axial compressibilities with increasing pressure: b is the most compressible direction near
232 ambient pressure, but the stiffest at pressures exceeding 30 GPa. This change in relative
233 compressibility is reflected in extrema in the variation of lattice parameter ratios versus pressure,
234 which occur at 13 GPa (b/c) and 33 GPa (a/b). The largest deviation in atomic coordinates
235 between our results and experiment occurs for the position of the H atom, corresponding to an
236 OH bond length of 1.02 Å for our results as compared with 0.85 Å for experiment (Bolotina et
237 al. 2008). Overestimation of OH bond length is expected at our level of theory (Santra et al.
238 2009).

239

240 The elastic moduli change discontinuously at the high-spin to low-spin transition and
241 continuously at the symmetrization transition (Fig. 6). Because the hydrogen bonds lie within the
242 xy -plane, the difference between asymmetric and symmetric structures is reflected more strongly
243 in c_{11} and c_{22} than in c_{33} , and more strongly in c_{66} than in c_{44} or c_{55} . Values of c_{ijkl0} and c'_{ijkl0}
244 show that the elastic moduli are softer and vary more rapidly with pressure in the asymmetric
245 state as compared with the symmetric state: while the elastic moduli of the asymmetric and
246 symmetric states become identical at the symmetrization transition, the pressure-dependence of
247 the elastic moduli changes discontinuously at the transition. The elastic moduli are all stiffer in
248 the low-spin state as compared with the high-spin state (Table 2). The c_{44} and c_{55} elastic moduli
249 show a non-monotonic pressure dependence.

250

251 The bulk and shear moduli increase monotonically with increasing pressure from 0 to 90 GPa
252 and both undergo an increase of 18% at the spin transition (Fig. 7). In the low spin state, the
253 shear modulus is nearly independent of pressure, reflecting, in part, the non-monotonic

254 dependence of c_{44} and c_{55} on pressure, while c_{66} increases with increasing pressure. Our elastic
255 constants for the low spin state are in good agreement with previous calculations (Thompson et
256 al. 2017) with differences ($< 7\%$) reflecting the difference in exchange-correlation functional
257 used in the two studies (PBE vs. PBEsol in our study). We find that ϵ -FeOOH is highly
258 anisotropic in both longitudinal- and shear-wave velocities at all pressures, with the shear wave
259 velocity varying with propagation and polarization direction by as much as 24% at zero pressure
260 and 43% at 46 GPa.

261

262 The evolution of the hydrogen bond on compression is clearly reflected in the vibrational
263 frequencies (Fig. 8). The frequencies of the A_1 and B_2 OH stretching modes decrease rapidly
264 with pressure and the bending modes increase more gradually with pressure so that the
265 frequencies of these two branches approach each other. In the symmetrically-bonded phase the
266 OH stretching mode frequencies increase with increasing pressure while the bending mode
267 frequencies initially continue to increase slightly with increasing pressure. These trends are also
268 seen in δ -AlOOH (Tsuchiya et al. 2008). The OH stretching and bending mode frequencies
269 change little at the high-spin to low-spin transition; in the low spin state some of the bending
270 mode frequencies decrease with increasing pressure. Agreement is excellent between our
271 bending mode frequencies and experiment (Thompson et al. 2020) and our stretching mode
272 frequencies are 1.4% smaller than the positions of peaks apparent in the experimentally reported
273 spectrum in the OH stretching region at ambient conditions. Underestimation of OH stretching
274 frequencies is expected at our level of theory (Santra et al. 2009).

275

276 The predicted absolute intensities of the IR- and Raman-active modes show large changes in the
277 vibrational spectra with increasing pressure (Fig. 9). Factor group analysis for the $P2_1nm$ and
278 $Pnnm$ structure shows that the irreducible representation of the zone center optic vibrations are
279 $\Gamma_{P2_1nm} = 7A_1(IR, R) + 4A_2(R) + 3B_1(IR, R) + 7B_2(IR, R)$ and $\Gamma_{Pnnm} = 2B_{1u}(IR) +$
280 $5B_{2u}(IR) + 5B_{3u}(IR) + 3A_u + 2A_g(R) + 2B_{1g}(R) + 1B_{2g}(R) + 1B_{3g}(R)$, where IR and R
281 denote infrared and Raman active modes. In the IR spectrum, the highest frequency peak initially
282 increases in intensity with increasing pressure, then splits as symmetrization is approached. At a
283 pressure that nearly coincides with symmetrization (33 GPa), the most intense peaks are no
284 longer the highest frequency peaks, reflecting mixing of stretching and bending modes. In the
285 low-spin state, the peak at the highest frequency become the one with the highest intensity again.
286 The Raman spectrum also shows splitting of the OH highest frequency as symmetrization is
287 approached, as well as a vanishing intensity. This decrease in intensity is expected on symmetry
288 grounds, and is also seen, for example, in H₂O (Goncharov et al. 1999).

289

290 The electronic density of states shows a finite band gap at all pressures in high-spin and low-spin
291 states (Fig. 10). The band gap decreases with increasing pressure in both phases and increases by
292 0.15 eV at the high-spin to low-spin transition. The band gap is narrow and comparable to that
293 typically seen in semiconductors: 1.9 eV at ambient pressure and 1.3 eV at the highest pressure
294 explored in this study. Consideration of +U in our study is crucial to obtaining agreement with
295 experiment: if we assume that U-J=0 eV, we find that there is no band gap at any pressure.

296

297

Discussion

298 We find two distinct phase transitions: the symmetrization transition and the high-spin to low-
299 spin transition, which do not coincide, but are well separated in pressure, with the high spin
300 symmetric phase stable over a finite pressure interval (8 GPa). Our results therefore do not
301 support the arguments of some earlier studies that symmetrization drives the high-spin to low-
302 spin transition (Gleason et al. 2013).

303

304 Our value for the pressure of the symmetrization transition (37 GPa), is much higher than the
305 value of 18 GPa, argued for by Thompson et al. (2020). However, Thompson et al. (2020) were
306 not able to measure hydrogen positions and relied on other lines of evidence to argue for the
307 pressure of symmetrization. These included the location of inflection points in the variation of
308 lattice parameter ratios with pressure. However, we do not see inflection points but instead find
309 local extrema (a local minimum in b/c at 13 GPa, and a local maximum in a/b at 33 GPa) neither
310 of which correspond precisely with the pressure of hydrogen bond symmetrization. We find that
311 the lattice parameters begin to vary nearly linearly with pressure at the symmetrization transition,
312 behavior also seen in a previous theoretical study of δ -AlOOH (Tsuchiya and Tsuchiya, 2009).

313

314 The asymmetric to symmetric transition is continuous. The volume and bulk modulus (and all
315 the elastic moduli) are continuous across the transition, so the transition is neither first order nor
316 second order. Elastic wave velocities are also continuous across the symmetrization transition, so
317 that no seismological signature of the symmetrization transition is expected. Our computed
318 vibrational spectra indicate that symmetrization might be detected via IR or Raman
319 spectroscopy: according to our results, the symmetrization transition is characterized by changes
320 in the pressure dependence of several modes, as well as splitting, and changes in intensity.

321 Neutron diffraction of deuterated samples, as recently done for AlOOH (Sano-Furukawa et al.
322 2018), could also lend further insight into symmetrization in ϵ -FeOOH.

323

324 Our predictions of the shear and bulk modulus of ϵ -FeOOH do not agree with the experimental
325 measurements of Ikeda et al. (2019). The contrast in the pressure dependence of the shear
326 modulus ($G' = dG/dP$) is particularly notable ($G' = 1.2$ from our results vs. $G' = 4.6$ from
327 experiment). The reason for this discrepancy is unclear. It is possible that approximations to the
328 exchange-correlation functional in our study are the cause of the discrepancy, but this seems
329 unlikely, because previous studies have found good agreement between density functional theory
330 and experiment for the elastic moduli of δ -AlOOH (Tsuchiya and Tsuchiya 2009). The value of
331 G' found for δ -AlOOH (1.33) is very similar to what we find for ϵ -FeOOH. Another possibility
332 is that the experimental sample is textured or that the degree of texture of the sample varied with
333 increasing pressure. Texturing of the sample could change the shear modulus substantially
334 because ϵ -FeOOH is very anisotropic, with the shear modulus varying by 24% to 43% with
335 propagation and polarization direction at 0 and 43 GPa, respectively. ϵ -FeOOH is much more
336 anisotropic than δ -AlOOH (Tsuchiya and Tsuchiya 2009).

337

338 The high spin state is likely to remain magnetically ordered at room temperature throughout
339 its stability field. This conclusion is based on the large enthalpy difference that we find between
340 AFM and FM ordering. The enthalpy difference grows with increasing pressure and is similar in
341 magnitude to the difference between the AFM and FM ordering states of hematite (0.25 eV/Fe;
342 (Rollmann et al. 2004)), which has a Neel temperature of 950 K. We would therefore expect ϵ -
343 FeOOH to have a Neel temperature of similar magnitude based on our results, in agreement with

344 neutron diffraction experiments that show that AFM ordering exists in ϵ -FeOOH to at least 423
345 K (Pernet et al. 1975) and an estimated Neel temperature of 570 K (Pernet et al. 1973). The low
346 spin state is likely to be magnetically disordered at room temperature, as the difference in energy
347 between AFM and FM ordering is much smaller than in the high spin state (by a factor of ~ 25).
348

349 Our results suggest possible explanations for the sharpness of the high-spin to low-spin transition
350 as seen experimentally. The experiments of Thompson et al. (2020), show that the transition
351 interval is irresolvably sharp and no greater than 2 GPa. This is much less than the width of the
352 high-spin to low-spin transition at room temperature seen in other systems: for example, 10 GPa
353 in $\text{MgSiO}_3\text{-Fe}_2\text{O}_3$ (Liu et al. 2018), or 18 GPa in $\text{Mg}_{0.5}\text{Fe}_{0.5}\text{O}$ (Solomatova et al. 2016). We
354 hypothesize that the width of the high spin to low spin transition in ϵ -FeOOH is limited by two
355 factors. First is the presence of non-ideal interactions between high-spin and low-spin Fe cations.
356 We find that the mixed-spin state is much higher in energy than the high-spin or low-spin states.
357 This unfavorable energy of interaction is not included in the widely used ideal model of the spin
358 transition (Tsuchiya et al. 2006) and has the effect of limiting the pressure interval of coexistence
359 of high-spin and low-spin cations. Second is the presence of magnetic order. The ideal solution
360 model, as typically applied, assumes the high temperature limit of magnetic entropy. But this
361 limit may not be valid in the case of ϵ -FeOOH because the Neel temperature of the high-spin
362 state is likely to exceed room temperature at all pressures.

363

364 Our calculations are quasiharmonic and we are therefore not able explore the possibility of H
365 disorder in ϵ -FeOOH. Consideration of H disorder is motivated by neutron diffraction
366 experiments on δ -AlOOH, which have been interpreted to show disorder of H between two

367 symmetrically equivalent positions along the O···O line (Sano-Furukawa et al. 2018). On the
368 other hand, another recent study based on static structural relaxations in density functional theory
369 and nuclear magnetic resonance experiments argues against H disorder in δ -AlOOH (Trybel et
370 al. 2021). We suggest that molecular dynamics simulations could be used to explore the
371 possibility of H disorder in ϵ -FeOOH.

372

373

Implications

374 The presence of ϵ -FeOOH in Earth's mantle could have significant effects on material properties
375 due to the iron spin-transition and hydrogen bond symmetrization. The shear modulus shows a
376 large increase at the high-spin to low-spin transition in ϵ -FeOOH (an 18% increase in shear
377 modulus, or 3% increase in shear wave velocity); behavior that contrasts with other systems. For
378 example, in ferropicriolite, the shear modulus is continuous across the high-spin to low-spin
379 transition (Yang et al. 2015; Marquardt et al. 2018). Possible seismic detection of the high-spin
380 to low-spin transition in the mantle has therefore focused on the effect of the transition on the
381 bulk modulus, and therefore the P-wave velocity (or bulk sound velocity) (Shephard et al. 2021).
382 Our results show that the S-wave velocity may also be significantly affected by the spin
383 transition in lower mantle phases other than ferropicriolite. The bulk modulus anomaly
384 associated with the high-spin to low-spin transition is caused by the volume collapse across the
385 pressure interval of the transition. We have assumed in the case of ϵ -FeOOH, that the high-spin
386 to low-spin transition is sharp, consistent with experiment, and therefore does not show any bulk
387 modulus anomaly at room temperature, although it is possible that a narrow transition interval
388 exists over which the bulk modulus anomaly would also exist.

389 Based on our results, the seismic signature of the spin transition in phase H may be more distinct
390 than that in other systems undergoing spin transitions, including ferropericlase. In ferropericlase,
391 the width of the transition is broader than the ideal case at all temperatures because of favorable
392 interaction between high-spin and low-spin Fe (Holmström and Stixrude 2015), tending to mute
393 the elastic signature of the transition. The width of the spin transition in ϵ -FeOOH is likely to
394 increase with temperature. However, the unfavorable interaction between unlike spins in ϵ -
395 FeOOH is likely to limit the width of the transition as seen in phase H as compared with
396 expectations based on ideal mixing of spin states.

397

398 Our prediction of a narrow band gap in ϵ -FeOOH raises the possibility that phase H may
399 contribute to the electrical conductivity of the lower mantle as seen in electromagnetic sounding
400 (Püthe et al. 2015). The narrow gap that we find is consistent with experimental observations of
401 non-zero infrared transmission at all pressures measured from 23-72 GPa (Thompson et al.
402 2020). Moreover, the experiments show increasing absorption with increasing pressure, in
403 agreement with the decreasing band gap with increasing pressure that we find. Our results are
404 also consistent with experimental measurements showing that the electrical conductivity
405 increases with increasing pressure and is small in value, typical of semi-conductors (Wang and
406 Yoshino 2021; Zhuang et al. 2022). On the other hand, the experiments show a rapid drop in
407 transmission and a rapid increase in electrical conductivity at the high-spin to low-spin transition,
408 whereas we find a slight increase in the band gap at the transition. Further study of the
409 relationship between the band structure, optical absorption, and electrical conductivity is
410 therefore warranted.

606

607 **Figure 1.** The structure of the $P2_1nm$ ϵ -FeOOH phase in an (a) AFM HS state, (b) FM HS state,
608 and (c) an AFM mixed-spin state. The solid black lines indicate unit cells, oxygen atoms are red
609 spheres, hydrogen atoms are pink spheres, and iron atoms are gold spheres. Blue arrows
610 represent the magnetic moment μ of the iron atoms. The arrow magnitude is related to the spin
611 state (longer = high-spin; shorter = low-spin) and the arrow direction is related to the up/down-
612 spin of valence electrons (up = $+\mu$; down = $-\mu$). Image generated using the software VESTA
613 (Momma and Izumi 2008).

614

615 **Figure 2.** Enthalpy of FM and AFM states at static condition with respect to the AFM low-spin
616 enthalpy. The arrow marks the pressure at which hydrogen bond symmetrization occurs, and x
617 marks the AFM mixed spin enthalpy.

618

619 **Figure 3.** O-H vs O-O bond distance in high-spin (circles) and low-spin (squares) states with
620 pressure indicated by the color bar. The 2:1 line is shown in black.

621

622 **Figure 4.** Pressure-volume equation of state for static and 300 K isotherms. Symbols in red,
623 orange, and plum represent the asymmetric high-spin phase, the symmetric high-spin phase, and
624 the symmetric low-spin phase at 300 K conditions. Dashed lines and solid lines represent the
625 static and 300 K equations of state for each respective color. The blue line follows the stable
626 phases. The vertical black dashed lines represent the hydrogen bond symmetrization and spin
627 transition at 37 GPa and 45 GPa, respectively, at 300 K. Equation of state fit parameters V_0 , K_0 ,
628 and K_0' are 65.68 \AA^3 , $168.55 \pm 0.30 \text{ GPa}$, and 3.72 ± 0.01 for asymmetric high-spin, 64.48 \AA^3 ,

629 193.42 ± 0.43 GPa, and 3.51 ± 0.02 for symmetric high-spin, and 56.65 \AA^3 , 236.56 ± 0.42 GPa,
630 and 3.91 ± 0.01 for the symmetric low-spin at 300 K.

631
632 **Figure 5.** Lattice parameter ratios with respect to pressure. Red and plum represents the AFM
633 high-spin and AFM low-spin states, respectively, and are compared to experimental results
634 (white symbols). The vertical dashed lines represent the predicted 300 K pressure of the
635 symmetrization transition (lower pressure) and the high-spin to low-spin transition (higher
636 pressure).

637
638
639
640 **Figure 6.** Elastic modulus with respect to pressure. Red and plum represent the AFM high-spin
641 and AFM low-spin states, where closed and open symbols represent the asymmetric and
642 symmetric states, respectively. Symbols representing stable phases are outlined in black.

643
644 **Figure 7.** Left: Elastic properties of ϵ -FeOOH with respect to pressure compared with
645 experimental measurements from Ikeda et al. (2019) (white circles and squares correspond to
646 bulk and shear modulus, respectively). Dotted plum lines are maximum and minimum values of
647 shear modulus from single crystal wave velocities from our results. Right: v_p and v_s dependence
648 on propagation direction at 3.4 GPa (solid), 23.3 GPa (dashed), and 94.4 GPa (dotted).

649
650 **Figure 8.** Pressure dependence of optical mode frequencies compared to experimental data in
651 white circles (Thompson et al., 2020).

652
653 **Figure 9.** Computed IR intensities (left) and Raman intensities (right) with respect to pressure.

654

655 **Figure 10.** Electronic density of states at 3.4 GPa (top) and 94 GPa (bottom) with respect to s, p,

656 and d orbitals. Inset shows the band gap dependence on pressure.

657

658 Table 1. Crystal structures of the $P2_1nm$ and $Pnmm$ phase with respect to pressure.
