21   **ABSTRACT**

22   The systematic mineralogy of niobium (Nb) is complex with more than one hundred species

23   dominated by multicomponent oxides of similar chemistry. The determination of Nb speciation in

24   solids (i.e. the distribution between the phases present and the crystal-chemical environment of Nb)

25   is thus a challenge in geological contexts. Here, we present the first Nb $L_{2,3}$-edges X-ray absorption

26   near-edge structure (XANES) measurements on a variety of Nb minerals and synthetic oxides with

27   geological relevance. The interpretation of Nb $L_{2,3}$-edges XANES spectra in the light of crystal-field

28   theory shows the sensitivity of spectra to local site symmetry and electronic environment around Nb

29   atoms. Crystal-field multiplet simulations give estimates of the $10Dq$ crystal-field parameter values

30   for Nb^{5+}, which range from 2.8 to 3.9 eV depending on Nb coordination and Nb–O distances.

31   Rather than a $10Dq$ vs. R^{-5} relationship (where R represents the average Nb–O bond distance)

32   expected in a point-charge model, we find a R^{-3} dependence with the crystal-field splitting for

33   reference materials with octahedrally-coordinated Nb. Complementary ligand-field multiplet

34   simulations provide evidence of charge transfer between Nb and O. The contribution of the ionic

35   and covalent characters to the Nb–O bonds is equivalent, unlike more ionic $3d$ metal–O bonds. This

36   systematic characterization of the $L_{2,3}$-edges XANES spectral properties of Nb provides information

37   on the mechanisms by which Nb^{5+} substitutes for Fe^{3+}, Ti^{4+} or Ce^{4+} in oxides common in geological

38   contexts. Whereas the substitution of Nb^{5+} for Ce^{4+} does not modify the local structure of the cation

39   site in cerianite, the substitution of Nb^{5+} for Ti^{4+} in rutile and anatase results in an increase of the

40   cation-ligand distance and a decrease in the symmetry of the cation site. Conversely, the

41   substitution of Nb^{5+} for Fe^{3+} in hematite and goethite results in a smaller cation site distortion. Our

42   study demonstrates the usefulness of $L_{2,3}$-edges XANES spectroscopy to determine Nb speciation in

43   minerals in order to understand the processes of enrichment of this critical metal.

44   **Keywords:** Niobium, XANES, multiplet, $10Dq$, local structure, speciation

45

INTRODUCTION

46

47   Niobium (Nb) is a quintessential critical element (European Commission 2020) used to

48 manufacture superalloys, superconducting magnets and catalysts (Schulz et al. 2017). Niobium-

49 based materials are also valued for the implementation of low-carbon technologies thanks to the

50 unusual properties that arise from defects in their crystal structure (Ismael 2020, Ma et al. 2020). An

51 increasing range of applications is expected to drive the future demand for Nb. This economic

52 importance is exacerbated by the scarcity of Nb deposits. The incorporation of Nb into most

53 common rock-forming minerals is limited by its low concentration on Earth (ca. 12 ppm in the

54 upper continental crust; Rudnick and Gao 2003) and its geochemical properties. Only Nb^{5+} occurs

55 under oxygen fugacities relevant to lithospheric and surficial environments (Cartier et al. 2015),

56 with the electronic configuration [Kr] $4d^0$. This high valence and small ionic radius (0.64 Å in

57 octahedral coordination; Shannon 1976) makes Nb a high-field-strength elements (HFSE) along

58 with Zr, Sn, Hf, Ta, Pb, Th and U.

59   Niobium concentrates in silicic melts during partial melting and fractional crystallization until

60 the precipitation of Nb minerals of the pyrochlore and columbite supergroups, which are among the

61 last phases to form in most crystallization sequences (Linnen and Cuney 2005). When such rocks

62 are exposed to weathering, the resistance of primary Nb minerals to alteration limits Nb leaching,

63 making it one of the most immobile elements (Hill et al. 2000). Thus, it is used as a reference

64 element for mass-balance calculations during weathering processes (Kurtz et al. 2000) or in

65 environmental studies (Nabi et al. 2021). The formation of the largest Nb deposits is a consequence

66 of this geochemical behavior, which leads to a significant residual enrichment during lateritic

67 weathering of primary deposits, typically by an order of magnitude relative to the parent rock

68 (Mitchell 2015).

69   Unambiguous identification of Nb minerals is needed to understand geological and

70 geochemical processes concentrating Nb such as magmatic differentiation (Walter et al. 2018; Lee

71 et al. 2006), metasomatic events (Wu et al. 2021) and supergene weathering (Lottermoser and

72   England 1988; Wall et al. 1996). However, the similar crystal chemistry and the frequent

73   metamictization of Nb minerals make the analysis of Nb speciation using X-ray diffraction analyses

74   challenging. The most abundant phases are multicomponent oxides with the general formulas

75   AB_2O_6 (columbite-group minerals: e.g. columbite, euxenite, aeschynite) and $A_{2-x}B_2O_7$ (pyrochlore-

76   group minerals: pyrochlore, betafite, samarskite). The eight-fold coordinated A-site, a square

77   antiprism, can be occupied by rare-earth elements (REE), Ca, U, Th, Fe, while the octahedral B-site

78   can be occupied by Ti, Nb, Ta and W and forms double chains in a zigzag pattern by sharing at least

79   two edges with neighboring octahedra (Ewing 1975). Due to strong interionic repulsion, most NbO_6

80   octahedra are distorted (Kunz and Brown 1995). Metamictization is common due to the presence of

81   radioactive elements (Zietlow et al. 2017). This process leads to the formation of local structures

82   made of corner-sharing octahedra at the expense of the edge-sharing linkages observed in

83   crystalline oxides (Ewing 1975).

84   Niobium is also found as a minor or trace element in oxide minerals. Hydrothermal events can

85   produce amorphous Fe oxides containing low amounts of Nb (Wu et al. 2021). In metasomatized

86   mantle peridotites, rutile may host more than 95 % of the Nb budget (Kalfoun et al. 2002). Niobium

87   can also be enriched in Fe- and Ti oxides that occur as veinlets or weathering products in laterites

88   (Lottermoser and England 1988; Giovannini et al. 2017). These oxides highlight the capacity of

89   Nb^{5+} to substitute for cations such as Ti^{4+}, Sn^{4+}, W^{6+}, Ce^{4+} and Fe^{3+} in various minerals (Černý and

90   Ercit 1989; Giovannini et al. 2017), which further complicates the determination of Nb speciation in

91   such geological contexts.

92   Here, we report the first systematic analysis of Nb $L_{2,3}$-edges XANES spectra using a selected

93   set of Nb minerals (fluorcalciopyrochlore, hydropyrochlore, niocalite, Nb perovskite, columbite)

94   and synthetic oxides (Nb_2O_5, lueshite and Nb-substituted hematite, goethite, rutile, anatase and

95   cerianite). So far, only a few $L_{2,3}$-edges XANES spectroscopic studies have been published on

96   synthetic Nb oxides and fluorides (Sugiura et al. 1988; Kubouchi et al. 2012; Wang et al. 2018).

97   The objectives of this work are thus twofold:

98   (1) To relate spectral properties to the local electronic structure of Nb in crystalline materials by

99   means of crystal-field and ligand-field multiplet (CFM and LFM) calculations. Such an

100   approach has proven to be useful to model the bioavailability and mobility of Fe in

101   terrestrial and subsurface environments (Bhattacharyya et al. 2019) and V speciation in

102   fresnoite (Höche et al. 2013).

103 (2) To investigate the processes by which Nb substitutes for Fe, Ti and Ce in oxides, which can

104   serve as models for the major Nb-bearing oxides found in geological contexts and used in

105   industry.

106   Overall, the present study on Nb speciation in geological contexts demonstrates how the

107 sensitivity of Nb $L_{2,3}$-edges XANES spectroscopy can be used to better characterize and understand

108 Nb mineralogy. In primary and lateritic deposits, deciphering Nb speciation will improve our

109 understanding of Nb enrichment and may help to diversify the range of primary sources and to

110 upgrade the efficiency of ore processing (Černý and Ercit 1989).

111   MATERIALS AND METHODS

112 **Mineral synthesis procedures**

113   **Niobium-substituted Fe oxides (1 wt% Nb).** The synthesis of Nb-bearing goethite (α-

114 FeOOH) has been adapted from the hydrothermal synthesis of Sc-bearing Fe oxides at 70 °C

115 (Chassé et al. 2017). Nb-bearing goethite was converted into Nb-bearing hematite (α-Fe$_2$O$_3$) by

116 dehydroxylation at 300 °C for 2 h. The solid was washed using H$_2$SO$_4$ in order to remove potential

117 adsorbed Nb species and poorly-crystallized material.

118   **Niobium-substituted Ti oxides (5 wt% Nb).** The synthesis of Nb-bearing anatase (TiO$_2$) has

119 been carried out using a sol-gel method at moderate temperature (Dufour et al. 2012). Niobium-

120 bearing rutile (5 wt%) was obtained by heating Nb-bearing anatase (5 wt%) at 700 °C for 3 hours.

121 Niobium-bearing anatase samples with 1 and 10 wt% Nb were also synthesized following this

122 procedure.

123   **Niobium-substituted cerianite (1 wt% Nb).** Niobium-bearing cerianite was synthesized

124   using a high temperature solid-state reaction at 1,300 °C by homogenizing CeO_2, Nb_2O_5 and Nd_2O_3

125   powders (Olegário et al. 2013).

126   **Lueshite.** This reference material was obtained by following a hydrothermal synthesis

127   procedure at 200 °C over 24 h based on the experimental procedure of Gouget et al. (2019).

128   **Analytical methods**

129   **Powder X-ray diffraction (XRD) analyses.** The successful completion of the syntheses was

130   verified by X-ray diffraction analysis. X-ray diffraction was performed using a PANALYTICAL

131   X'pert Pro MPD diffractometer. Measurements were carried out in Bragg-Brentano geometry using

132   a Co Kα anode in order to minimize the X-ray absorption of Fe in hematite and goethite. Data were

133   recorded with an X'Celerator detector between 3 °2θ and 90 °2θ with 0.017 ° steps. The incident

134   beam mask was fixed at 20 mm and the Soller slits at 0.04 rad. Total counting time of measurement

135   was 3 hours per sample. The crystal structure of synthetic compounds was checked using the

136   International Centre for Diffraction Data (ICDD) references (PDF-2 database). No secondary

137   niobian phase was detected on the XRD patterns of Nb-bearing Fe, Ti and Ce oxides confirming

138   that the Nb ions were incorporated into the crystal lattice and substituted for Fe, Ce and Ti

139   (Supplemental Figs. S1 and S2).

140   **Single-crystal XRD.** Single-crystal X-ray diffraction data were acquired on natural Nb

141   reference materials using an Agilent Diffraction Xcalibur-S diffractometer equipped with a

142   Sapphire CCD-detector with Mo K-α1 radiation (λ = 0.71073 Å, graphite monochromator) at

143   293 K. Data reduction, cell refinement and space group determination were performed using the

144   CrysAlisPro software.

145   **Electron microprobe (EMP) analyses.** Electron microprobe (EMP) analyses were used to

146   determine the crystal chemistry of the Nb reference materials sourced from mineralogical

147   collections. Analyses were conducted on a CAMECA SX Five electron probe at the CAMPARIS

148   facility (Sorbonne Université, Paris). After checking the homogeneity of the samples, two to seven

149   spots were probed on each sample at 15 kV and 40 nA for the major elements and at 15 kV and

150   299 nA for minor and trace elements. Wavelength-dispersive spectroscopy analyses were performed

151   using the following standards: albite for Na, diopside for Mg, Si and Ca, orthoclase for Al and K,

152    $MnTiO_3$ for Mn and Ti, hematite for Fe, $BaSO_4$ for Ba, topaz for F, $LiNbO_3$ for Nb, metallic Ta for

153   Ta, SrSi for Sr, zircon for Zr, galena for Pb, monazite for Th, uraninite for U and allanite-(Y) for Y,

154   La, Ce, Nd.

155   **Acquisition of X-ray absorption spectra.** Niobium L_3-edge (2360–2390 eV) and L_2-edge

156   (2455–2485 eV) XANES spectra were recorded on LUCIA beamline at SOLEIL synchrotron

157   radiation facility (Gif-sur-Yvette, France) operating with a storage ring current of 450 mA and

158   energy of 2.75 GeV (Vantelon et al. 2016). A Si(111) double-crystal monochromator was used with

159   an energy resolution of 0.25 eV at 2400 eV (Schaefers et al. 2007). The monochromator was

160   calibrated at the energy of the Nb L_3-edge using Nb_2O_5. Due to the high Nb content of Nb minerals,

161   spectra were recorded on cellulose-diluted pellets before being mounted on a holder. Pure pellets

162   were used for synthetic Nb-substituted samples. Data were collected between 2300 and 2550 eV at

163   room temperature, under vacuum, in fluorescence mode. Energy steps were (2, 0.2, 1, 0.2, 1) eV for

164   energy ranges of (2300–2350), (2350–2400), (2400–2455), (2455–2490) and (2490–2550) eV,

165   respectively, with a 1 s integration time. Two measurements per sample were sufficient to obtain a

166   good signal-to-noise ratio and check the reproducibility of the edge features.

167   **Data processing and simulations**

168   **Processing of X-ray absorption data.** Data were processed using the Larch software

169   (Newville 2013). The MBACK normalization algorithm was applied to prevent distortion in the

170   XANES data and preserve the branching ratio (Weng et al. 2005). This method applies a single

171   smooth background function over the entire $L_{2,3}$-edges data range rather than normalizing each edge

172   independently. The normalization function is a first order Legendre polynomial (Supplemental Fig.

173   S3) and the edge energy chosen as the input parameter of the MBACK function implemented in

174   Larch is 2371 eV. The spectra of Nb-substituted hematite, Nb-substituted goethite, lueshite and

175   niocalite were trimmed beyond 2475 eV because the S K-edge hides the high-energy features of the

176   Nb L_2-edge.

177   Niobium $L_{2,3}$-edges XANES features were fitted using three pseudo-Voigt functions in order to

178   quantitatively compare and retrieve differences in the three features between the spectra. The

179   continuum background was removed using an error function with fixed inflection points (2373.0

180   and 2467.0 eV) and large width (ca. 8 eV) to reproduce the slow onset of the electronic continuum

181   (Brotton et al. 2007). No agreement or convention exists regarding the parameters of the

182   background functions (Henderson et al. 2014) but similar procedures have been applied to Fe $L_{2,3}$-

183   edges (Bourdelle et al. 2013) and Zr $L_{2,3}$-edges (Jollivet et al. 2013). An error function was

184   preferred over the commonly-used arctangent because its width is related to the instrumental

185   resolution rather than to the lifetime of the excited state, which is not known a priori. Because the

186   best mathematical fits were obtained for a relative weight of Lorentzian to Gaussian components

187   between 0.8 and 1.0 depending on the spectra, this parameter was fixed to 0.9 in all fits for

188   comparative purposes.

189   **Calculations of crystal-field and ligand-field multiplets.** Simulations of the Nb $L_{2,3}$-edges

190   spectra were performed using the Crispy software as implemented in the Quanty library (Haverkort

191   2016; Retegan 2019). Two approaches were tested to reproduce the spectral features. The first is a

192   CFM calculation which takes into account the crystal-field effects acting on Nb. Ligand-field

193   multiplet calculations offer a more comprehensive model by including ligand-to-metal charge

194   transfer, i.e. by mixing in the ground state the $4d^0$, $4d^1\underline{L}^1$, $4d^2\underline{L}^2$, $4d^3\underline{L}^3$ configurations through a

195   hybridization Hamiltonian (more details on this notation are provided in Supplemental Material).

196   Crystal- and ligand-field multiplet calculations both require specific input parameters. To

197   account for the lifetime broadening, Lorentzian functions with a full width at half-maximum of

198   1.66 eV and 1.87 eV for the L_3 and L_2-edges were used to simulate the features (Krause and Oliver

199   1979). The experimental Gaussian broadening was set to ca. 1.5 eV to best reproduce the

200   experimental spectra. The simulations of the experimental spectra were carried out by finding the

201 best scaling factors for the Slater-Condon integrals that best account for direct and exchange

202 interactions between the $2p$–$4d$ orbitals ($F^2_{pd} = 2.680$ eV, $G^1_{pd} = 1.627$ eV and $G^3_{pd} = 0.946$ eV for

203 the free ion). The reduction of these values modifies the relative intensity of the features. The values

204 of the $4d$ and $2p$ spin-orbit coupling parameters were kept close to the atomic values of 0.124 eV

205 and 63.97 eV. The crystal-field splitting parameter ($10Dq$) was chosen to best reproduce the energy

206 difference between the two features, which corresponds to the splitting of the final state of the d

207 orbitals. The extra parameters required for LFM calculations are the hybridization strength V_{mix}

208 (V_{t2g}, V_{eg}), the configuration-averaged energies of the charge transfer configuration (E($4d^1\underline{L}^1$)–

209 E($4d^0$)) Δ, the core-hole potential U_{dc} and the average Coulomb interaction energies of a

210 corresponding electron pair U_{dd}. Detailed explanations of these parameters and their influence on

211 the spectral shapes are given in Supplemental Material (Supplemental Fig. S7).

212   **RESULTS**

213 **Characteristics of niobium $L_{2,3}$-edges XANES spectra**

214   The Nb $L_{2,3}$-edges XANES spectra (Fig. 1) are characterized by a split edge feature with two

215 peaks (A and B features) followed by a peak of lower intensity, ca. 10 eV after the edge (C feature),

216 as reported for other Nb-bearing materials (Sugiura et al. 1988; Wang et al. 2018). The energy of

217 the L_3-edge features (A_3, B_3, C_3) varies around ca. 2372, 2376 and 2387 eV, respectively (Fig. 1a).

218 The energy of the L_2-edge features (A_2, B_2, C_2) varies around ca. 2466, 2470 and 2481 eV,

219 respectively (Fig. 1b). At the L_3-edge, the energy position and width of the A_3 feature are stable. For

220 the B_3 features, these characteristics are prone to variations depending on the reference materials.

221 The spectra of niocalite, Nb-substituted hematite and Nb-substituted goethite show narrower B_3

222 features than the other reference materials. In contrast, the wide B_3 feature of Nb perovskite spectra

223 shows a shoulder at high energy (B'_3 at 2379–2380 eV, Fig 2h). In all compounds, C_3 is of lower

224 intensity than A_3 and B_3 with limited variation in position and width. Similar trends are observed at

225 the L_2-edge.

226   **Analysis of the niobium $L_{2,3}$-edges XANES spectra**

227   **Variation of the edge splitting.** The ΔE parameter, corresponding to the energy splitting

228   between the A and B features, ranges from ca. 2.6 to 4.0 eV at the L_3-edge and from ca. 2.3 to

229   4.0 eV at the L_2-edge (Table 2). Lueshite, Nb perovskite, fluorcalciopyrochlore and

230   hydropyrochlore spectra have the largest ΔE values (ranging from ca. 3.6 to 4.0 eV). Most spectra

231   have ΔE values between ca. 3.1 and 3.5 eV except for Nb-substituted cerianite spectra (ca. 2.6 and

232   2.3 eV at the L_3- and L_2-edges, respectively). Overall, the energy splitting at the L_3-edge follows the

233   same trend ($R^2 = 0.94$) as the energy splitting at the L_2-edge (Supplemental Fig. S6a).

234   **Variation of the intensity ratio.** The intensity ratio between the A and B features (I_A/I_B)

235   varies between ca. 0.8 and 2.1. It is higher at the L_2-edge (1.43) than at the L_3-edge (1.07). In most

236   compounds, it ranges between ca. 1.0–1.2 and 1.4–1.6 at the L_3- and L_2-edges, respectively (Table

237   2). Intensity ratios of Nb-substituted cerianite and Nb_2O_5 spectra are below 1 at the L_3-edge (Fig.

238   2g). There is a strong positive correlation of this parameter between the two edges ($R^2 = 0.95$,

239   Supplemental Fig. S6b).

240   **Variation of the bandwidth.** The ratio of the full width at half maximum of feature B with

241   respect to feature A ($FWHM_{B/A}$), ranges between ca. 1.0 and 2.2 for both edges. The spectra of Nb-

242   substituted goethite and hematite (Fig. 2c, 2d) have the lowest $FWHM_{B/A}$ values (ca. 1.1 and 1.4 at

243   the L_3- and L_2-edges, respectively). Most spectra exhibit intermediate $FWHM_{B/A}$ values (ca. 1.4–1.7

244   and ca. 1.6–1.9 at the L_3- and L_2-edges, respectively). The spectra of Nb perovskite (Fig. 2h) stands

245   out by its high $FWHM_{B/A}$ value (ca. 2.1 and 2.4 at the L_3-and L_2-edges, respectively). Niobium-

246   substituted anatase spectra (Fig. 2f) are also characterized by high $FWHM_{B/A}$, especially at the L_2-

247   edge (ca. 1.8–1.9 eV). On average, the width ratios at the L_3-edge (1.54) are smaller than those at

248   the L_2-edge (1.73). The $FWHM_{B/A}$ parameter is correlated between the two edges ($R^2 = 0.93$ when

249   the lueshite spectra are excluded as they deviate from the general trend, Supplemental Fig. S6c)

250   **Multiplet calculations**

251   **Crystal-field multiplet calculations.** The spectral features of Nb-substituted cerianite and

252   hematite are well reproduced by considering Nb in a regular polyhedron (O_h) (Figs. 3a and 3b) with

253   crystal field values of 2.8 and 3.7 eV, respectively (Table 3). The spectra of hydropyrochlore and

254   Nb perovskite are best modeled with a $10Dq$ value of 3.9 eV, which reproduces the splitting

255   between the features (Figs. 3c and 3d). Nonetheless, the B' features of low intensity at 2379–

256   2380 eV are absent. The good reproduction of the intensity ratios of the spectra for Nb-substituted

257   cerianite, hematite and hydropyrochlore results from the reduction of the Slater-Condon integrals to

258   50 %, an indication that the contribution of the ionic and covalent characters to the Nb–O bonds is

259   equivalent. The high intensity ratios of Nb perovskite spectra (Table 2) are reproduced with Slater-

260   Condon integrals reduced to 35 %.

261   **Ligand-field multiplet calculations.** We calibrated our calculations using Nb-substituted

262   hematite spectra, which exhibit the simplest spectral features. Charge-transfer parameters (U_{dc}, U_{dd},

263   Δ, V_{mix}, Table 4) were chosen according to calculations done on Ti^{4+} ($3d^0$)-compounds (Okada and

264   Kotani 1993). The intensity of the features of Nb-substituted hematite spectra is improved and the C

265   feature at ca. 2385 eV is reproduced when charge transfers are considered (Fig. 4). We also

266   attempted to reproduce the B' features in the spectra of hydropyrochlore and Nb perovskite by

267   investigating the influence of the hybridization strength (V_{mix}) on the spectral shapes. Using the

268   same charge-transfer parameters, the LFM calculation fails to explain the coexistence of B' and C

269   features visible on these spectra (Fig. 5).

270   <div align="center">**DISCUSSION**</div>

271   *$L_{2,3}$-edges XANES spectroscopy mirrors the electronic environment of niobium*

272   **Spectral energy splitting, interatomic distances and site symmetry.** Niobium $L_{2,3}$-edges

273   correspond to transitions to empty $4d$ states, making them sensitive to crystal-field effects. In the

274   framework of crystal-field theory and given that O^{2-} is the ligand of Nb^{5+} in all of our reference

275   materials, ΔE is correlated with the $10Dq$ crystal-field parameter, and therefore mirrors Nb^{5+} site

276   geometry and ligand distances.

277   The ΔE values range between 3.3 and 4.0 eV for octahedrally-coordinated Nb^{5+}. The ΔE

278 variability among reference materials with Nb in octahedral environment is correlated with the

279 average interatomic distances ($R^2 = -0.80$), as expected from the relationship between $10Dq$ and the

280 inverse fifth power of the average interatomic distance (i.e. R^{-5}) (Fig. 6) in a point-charge model

281 (Burns 1993). Nonetheless, the experimental data are best fitted with a function proportional to R^{-3}

282 ($\chi^2 = 0.17$), rather than a function proportional to R^{-5} ($\chi^2 = 0.26$). Other studies indicate similar

283 deviation from the expected theoretical R^{-5} dependence with crystal-field splitting ($R^{-8.3}$ in

284 Lebernegg et al. 2008; R^{-2} in Wang et al. 2018). The energy splitting in the spectra of Nb-

285 substituted Ti oxides deviates from both R^{-3} and R^{-5} models, reflecting the difference between

286 probed Nb–O distances and theoretical Ti–O distances (Fig. 6).

287   Among reference materials with octahedral Nb, the spectra of Nb_2O_5 show the lowest ΔE

288 values (3.06 and 3.28 eV at the L_2- and L_3-edges, respectively), slightly higher than previously

289 reported (2.6 and 2.8 eV; Sugiura et al. 1988). Nb_2O_5 powders may differ from each other in the

290 nature and proportion of the polymorphs they contain (Pilarek et al. 2017). Unfortunately, the

291 material investigated by Sugiura et al. 1988 was not characterized by XRD. Our Nb_2O_5 reference

292 consists of several polymorphs in equivalent proportions, with two monoclinic structures (ca. 90 %

293 of NbO_6 octahedra and 10 % NbO_5 polyhedra: Andersson 1967) and an orthorhombic one (NbO_5

294 and NbO_7 polyhedra; Waring et al. 1973) (Supplemental Fig. S2c). The presence of these different

295 structures leads to variations in the local environment of Nb which may explain a lower splitting as

296 compared to the other octahedrally-coordinated Nb reference materials.

297   The ΔE value of cerianite spectra, in which Nb occupies a cubic site, is 6/9–7/9 times smaller

298 than in reference materials containing octahedral Nb (Table 2). Indeed, crystal-field splitting values

299 are lower than expected in cubic coordination ($10Dq_c$ is 8/9 of $10Dq_o$). Though not detected by

300 XRD (Supplemental Fig. S2b), the synthesis of Nb-substituted cerianite can also result in the

301 formation of trace amounts of tetrahedrally-coordinated fergusonite-(Ce) ([Ce, REE]NbO_4) due to

302 the low solubility of Nb in cerianite (Kolodiazhnyi et al. 2016). The theoretical crystal-field

303 splitting parameter of tetrahedral Nb^{5+} is even lower ($10Dq_t$ is 4/9 of $10Dq_o$) possibly explaining the

304   small ΔE value of spectra from cubic Nb-substituted cerianite.

305   The splitting of the main edge of $4d^0$ elements increases with increasing cation charge. For

306   Zr^{4+}, Nb^{5+} and Mo^{6+} coordinated to oxygen ligands in weakly distorted octahedra, it is 3.2 eV

307   (Galoisy et al. 1999), 3.5–3.9 eV (this study) and 4.5 eV (Bare et al. 1993), respectively. This trend

308   highlights the decrease of the ionic radius with increasing cation charge ($^{[6]}Zr^{4+} = 0.72$ Å,

309    $^{[6]}Nb^{5+} = 0.64$ Å, $^{[6]}Mo^{6+} = 0.59$ Å; Shannon 1976) demonstrating the high sensitivity of $L_{2,3}$-edges

310   XANES spectroscopy to the speciation of $4d^0$ elements.

311   **Spectral broadening, charge transfer and site distortion.** It is necessary to consider the C

312   features in the fitting procedure in order to avoid an overestimation of the broadening of the B

313   features. Unlike their assignment to $2p \rightarrow 5s$ transitions (Sugiura et al. 1988), our LFM calculations

314   show that this feature results from hybridization between the $4d$ orbitals of Nb^{5+} and the $2p$ orbitals

315   of O^{2-}, in agreement with the work of Okada and Kotani (1993) on Ti compounds.

316   The spectra of Nb minerals have a high-energy shoulder of varying intensity at 2378 eV. The

317   high degree of distortion of NbO_6 octahedra in columbite and niocalite (Table 1) is not obvious

318   from the fit of their XANES spectra. However, both compounds have a shoulder (labelled B') of

319   limited intensity (Fig. 1). Furthermore, spectra of Nb perovskite and pyrochlore display the most

320   intense B' shoulder yet these reference materials are composed of regular octahedra. The intensity

321   of the shoulder is therefore not directly related to the distortion of the NbO_6 octahedra. Spectra of

322   Nb perovskite exhibiting the most intense C feature are also those with the largest B' shoulder. We

323   therefore ascribe the B' shoulder to orbital hybridization. The failure of ligand-field multiplet

324   calculations to reproduce both B' and C features (Fig. 5) may be due to the differences between the

325   Ti^{4+} charge-transfer parameters used here and those of Nb^{5+}, which are unknown (Okada and Kotani

326   1993).

327   The distortion of the cation site causes a broadening of the XANES features for Ti^{4+} and Zr^{4+}

328   (De Groot et al. 1992; Ikeno et al. 2013; Jollivet et al. 2013). In contrast, the broadening of the Nb

329    $L_{2,3}$-XANES features, probed by the $FWHM_{B/A}$ parameter, is determined by charge-transfer effects

330   and does not correlate with the degree of distortion of the NbO_6 octahedra. We conclude that the

331   significant contribution of charge-transfer effects to Nb $L_{2,3}$-XANES spectra is related to the

332   covalent character of the Nb–O bonds (Ikeno et al. 2011).

333   The spectra of Nb-substituted anatase and rutile display the poorest fit quality ($\chi^2 = 0.2$–0.5)

334   due to poor fitting of the wide B features characterized by slightly convex downward slopes. These

335   compounds have a weak shoulder at 2378 eV, suggesting the limited effect of charge transfer on the

336   spectra. In addition, another type of broadening is observed at the B feature (2376–2377 eV) which

337   could reflect the distortion of the Nb sites (Fig. 2f). In contrast, only the spectra of Nb-substituted

338   hematite and goethite exhibit A and B features of similar widths, suggesting a symmetrical Nb site

339   rather than the low symmetry of Fe^{3+} expected in the highly distorted FeO_6 octahedra. This

340   hypothesis is supported by the good reproduction of the spectra of Nb-substituted hematite in O_h

341   symmetry using LFM calculations. Despite the different Fe environments and crystal structures of

342   hematite and goethite, their spectral similarities indicate that the effect of distinct ligands (OH^- vs

343   O^{2-}) or changes in the octahedra arrangements (face-, edge- or corner-sharing) are negligible

344   compared to those of the site symmetry and average Nb–O distances.

345   **Spectral intensity variations and bond covalence.** The intensity ratios (I_A/I_B) exhibit low

346   standard deviations in our dataset ($\sigma = 0.13$ and 0.20 at the L_3- and L_2-edges, respectively). The low

347   intensity ratio of the L_3-edge spectrum of Nb-substituted cerianite (0.75) stands out from the other

348   reference materials (1.10 on average for references with octahedrally-coordinated Nb). This can be

349   explained by approximating the intensity ratio to the number of unoccupied states, i.e., 2/3 or 3/2 in

350   regular cubic and octahedral coordination, respectively (Ogasawara et al. 2001). The intensity ratios

351   retrieved from the fitting procedure are not equal to the statistical values because of ligand-field

352   multiplet effects (Ogasawara et al. 2001). However, the intensity ratio at the L_2-edge of the

353   reference materials with octahedrally-coordinated Nb is close to the statistical value of 3/2 (1.46 on

354   average) because this edge is less affected by multiplet effects (De Groot, 1994).

355   The significance of multiplet effects can be estimated from our simulations through the

356 reduction factor of the Slater-Condon integrals. The range of values of the reduction factor (0.35–

357 0.54) indicates a major contribution from the covalent nature of the Nb–O bonds. These values are

358 remarkably low compared to those around 0.7–0.8 observed in most oxides of $3d$ elements (De

359 Groot 2005). The modeling of other Nb compounds, such as $CsNbF_6$, requires similar reduction of

360 these parameters down to 40 % (De Groot et al. 1994). Therefore, the reduction of the Slater-

361 Condon parameters mirrors the covalent nature of the bonds formed by $4d$ elements relative to $3d$

362 elements (Singh et al. 2017).

363 **Why combine L_2- and L_3-edges XANES spectroscopy?** As the spectral features are

364 correlated between the L_2- and L_3-edges (Supplemental Fig. S5), the in-depth analysis of only one

365 edge is sufficient to determine the coordination number of Nb^{5+} and characterize the Nb local

366 environment. However, the simulation of XANES spectra using CFM and LFM calculations cannot

367 be carried out on a single edge. The lower sensitivity of the L_2-edge to atomic-multiplets effects

368 involves several pairs of solutions of the $10Dq$ value and the reduction of Slater integrals that

369 satisfactorily reproduce the L_2-edge spectra. Only the joint modeling of both edges constrains the

370 reduction of the Slater integrals, because of their higher sensitivity to atomic-multiplet effects (De

371 Groot et al. 1994). The choice for the acquisition and analysis of one or combined edges depends on

372 the precision of the crystallographic information one wants to extract from the spectra.

373 **Mechanisms of niobium substitution in oxides**

374 **Niobium-substituted Ti oxides.** The discrepancy between the average Ti–O distance in the

375 host structure and the observed Nb–O distances points out specific mechanisms of substitution in

376 Nb-substituted TiO_2 oxides (Fig. 6). Estimation of the Nb–O distances in Ti oxides by interpolation

377 of the correlation between ΔE and R^{-5} gives values of ca. 2.03 Å for Nb-substituted anatase and

378 ca. 2.01 Å for Nb-substituted rutile. Such an increase of the Nb–O distances is expected from the

379 larger ionic radius of Nb with respect to Ti ($^{[6]}Nb^{5+} = 0.64$ Å and $^{[6]}Ti^{4+} = 0.605$ Å; Shannon 1976).

380 Moreover, the symmetry of the Nb^{5+} site in TiO_2 is reduced as evidenced by the broadening of the

381 B_3 and B_2 features (Fig. 2f and Table 2). Increasing Nb substitution leads to lower ΔE and higher

382 FWHM$_{B/A}$ (Table 2), indicating an increased distortion of the Nb sites and increased Nb–O

383 distances. Such distortion of Nb sites and an increase in Nb–O distances with increasing amounts of

384 Nb were also evidenced using EXAFS (1.98 Å and 1.99 Å for $Ti_{0.97}Nb_{0.03}O_2$ and $Ti_{0.92}Nb_{0.08}O_2$,

385 respectively; Gardecka et al. 2015). The mechanism allowing the incorporation of Nb^{5+} in rutile and

386 anatase is the formation of one Ti^{4+} vacancy for every four Nb^{5+} (Sheppard et al. 2006) following

387 conditions of equilibrium and electroneutrality as illustrated by the Kröger-Vink notation:

388 $$5[Ti_{Ti}^x] + 2[Nb_2O_5] = 4[Nb_{Ti}^\bullet] + [V_{Ti}''''] + 5[TiO_2] \,(1)$$
389   In geological environments, the substitution of Nb^{5+} for Ti^{4+} in Ti oxides is also expected to be

390 accommodated by interstitial Fe^{3+} in oxidized environments following the substitution

391 $2Ti^{4+} = Fe^{3+} + 2Nb^{5+}$ (Ruck et al. 1986) and by Fe^{2+} in reducing environments, according to

392 $3Ti^{4+} = Fe^{2+} + 2Nb^{5+}$ (Giovannini et al. 2020).

393   Recent EXAFS analyses have highlighted the splitting of the first shell into two Nb-O

394 contributions at 1.88 and 2.01 Å in Nb-substituted anatase (Ribeiro et al. 2020). The increase of

395 Nb–O distances up to ca. 2.01 Å in the latter study and this work could reflect the presence of

396 Nb_2O_5 clusters in Nb-substituted anatase and rutile (Atanacio et al. 2014), as the values of Nb–O

397 distances in Nb_2O_5 are also 2.01 Å (Table 1). Even if the formation of Nb_2O_5 clusters cannot be

398 excluded, the differences between the spectra of Nb_2O_5 and Nb-substituted TiO_2 (Table 2) indicate

399 that Nb clustering is not an important process.

400   **Niobium-substituted Fe oxides.** Octahedral Fe^{3+} and Nb^{5+} have similar ionic radii, 0.645 Å

401 and 0.64 Å, respectively. The substitution of Nb^{5+} for Fe^{3+} in goethite is isormorphous (Oliveira et

402 al. 2008). Charge balance may be maintained by substituting $5Fe^{3+}$ for $3Nb^{5+}$, which induces cation

403 vacancies. Our study shows that Nb-substituted Fe oxides can be reproduced by CFM and LFM

404 calculations in regular O_h site symmetry even though the initial Fe site has a C_3 symmetry (Figs. 3b

405 and 4b). The regularity of the NbO_6 octahedra is also supported by the absence of broadening of

406 features B_3 and B_2 (Fig. 2c). The alignment of their experimental ΔE values on the trend with

407 respect to theoretical Fe–O distances (Fig. 6) indicates that the average Nb–O distances are not

408 significantly modified with respect to the average Fe–O distances.

409   However, EXAFS data on Nb-substituted hematite indicate shorter Nb–O distances (1.87 and

410 2.05 Å) than the Fe–O distances in hematite (1.92 and 2.11 Å; Silva et al. 2009). The differences

411 between our results and those of Silva et al. (2009) could reflect the high amounts of Nb

412 incorporated in the Fe oxides they synthesized (5 and 10 wt% Nb) or the synthesis protocol. The

413 incorporation of Nb in Fe oxides may result in a symmetrization of the Nb site due to the relaxation

414 of the crystal structure around Nb arising from the induced cation vacancies.

415   **Niobium-substituted cerianite.** Charge and size differences (0.97 and 0.64 Å, for Ce^{4+} and

416 Nb^{5+} respectively; Shannon 1976) limit the substitution of Nb in cerianite. The substitution of Nb^{5+}

417 for Ce^{4+} was explained by the displacement of Nb^{5+} cations from ideal cubic symmetry, leading to

418 oxygen vacancies (Hiley et al. 2018). It has also been suggested that half of the Ce ions become

419 trivalent to account for charge balance (Kolodiazhnyi et al. 2016). The other half of the charge

420 compensation would be accommodated by interstitial oxygens (Kolodiazhnyi et al. 2016, Schaube

421 et al. 2019) according to:

422      $$[Nb_2O_5] + 2[Ce_{Ce}^x] = 2[Nb_{Ce}^\bullet] + [O_i''] + 2[CeO_2] \ (2)$$
423   Our simulation of Nb-substituted spectra in O_h point symmetry (Fig. 3a) indicates that a Nb^{5+}–

424 Nd^{3+} co-doping eases the charge balance equilibrium ($2[Ce^{4+}] = [Nb^{5+}] + [Nd^{3+}]$) and prevents

425 significant distortion of the Nb site by limiting the formation of interstitial oxygen and vacancies.

426   IMPLICATIONS

427 **Deciphering the origin of the properties of technological Nb-substituted materials**

428   Some of the synthetic Nb-bearing oxides investigated in this study are meeting technological

429 challenges associated with climate change mitigation or environmental decontamination (e.g.,

430 Ismael 2020; Ma et al. 2020). Among other applications, they are used for dye-sensitized solar cells

431 (Lü et al. 2010), Na-ion battery anodes (Usui et al. 2015), direct solar-to-fuel conversion (Fu et al.

432 2016), and catalysts for the removal of exhaust-gas nitrogen oxide (Lian et al. 2015). These

433 enhanced physico-chemical properties result from the presence of substituted Nb^{5+} leading to oxide

434 mobility and transport properties due to charge unbalancing, interstitial oxygen or vacancies. The

435 properties of these Nb materials may be rationalized by knowledge of the mechanisms of Nb

436 insertion, which can be unveiled by Nb $L_{2,3}$-edges XANES spectroscopy.

437 **Upgrading ore processing through quantitative Nb XANES spectroscopy**

438   The choice of Nb ore-processing strategies depends on the nature of the Nb minerals, their

439 degree of alteration and their crystal-chemical variability. It is essential to correctly characterize the

440 Nb ores to optimize ore processing (Černý and Ercit 1989). Niobium recovery from pyrochlore ores

441 using amine collectors is used in three processing plants worldwide (Guimarães and Weiss 2001).

442 Nevertheless, this process induces a significant loss of columbite and Nb-rutile between feed and

443 concentrate (Gibson et al. 2015). Moreover, a high concentration of Fe in pyrochlore, which is a

444 typical feature of hydropyrochlore, reduces its floatability and causes Nb loss during ore processing

445 (Chehreh Chelgani et al. 2012). Niobian rutile has also been identified in the world-class Nb deposit

446 of Araxá, but its significance in the overall Nb budget remains elusive (Neumann and Medeiros

447 2015). Therefore, Nb XANES spectroscopy may be a valuable tool for identifying Nb speciation in

448 ore minerals and optimizing ore-processing strategies.

449 **Unravelling Nb geochemical behavior in natural systems**

450   Recent findings in hydrothermal contexts (Andersson et al. 2018; Dietzel et al. 2019) and

451 near-surface conditions (Wall et al. 1996; Chakrabarty et al. 2013; Giovannini et al. 2017)

452 demonstrate the alteration of Nb minerals and question the presumed immobility of Nb (MacLean

453 and Barrett 1993). The sensitivity of Nb $L_{2,3}$-edges XANES spectroscopy opens the possibility to

454 track Nb mineral speciation in weathered Nb-enriched samples. It could also be used to determine

455 the mechanisms of alteration of primary Nb minerals and reveal the mechanisms of Nb

456 incorporation in newly-formed phases. A combination of bulk and micro-XANES analyses could

457 thus be used to enlighten the molecular-scale and geochemical factors that induce contrasted Nb

458   dynamics in supergene environments as has been done for rare-earth elements (Janots et al. 2015;

459   Chassé et al. 2019; Borst et al. 2020).

FIGURE CAPTIONS

472 Figure 1: (a) Niobium L_3- and (b) L_2-edge XANES spectra of the studied Nb minerals. The

473 coordination number of Nb ($^{[8]}$Nb and $^{[6]}$Nb) is specified. Vertical lines centered at 2372, 2376,

474 2387 eV at the L_3-edge and at 2466, 2470, 2481 eV at the L_2-edge evidence the variable position of

475 the B$_3$ and B$_2$ features. The spectra of niocalite, lueshite, Nb-substituted hematite and goethite were

476 trimmed beyond 2475 eV due to sulfur impurities resulting in an intense S K-edge feature at

477 2481 eV.

478 Figure 2: Deconvolution of Nb L_3-XANES spectra of (a) fluorcalciopyrochlore,

479 (b) hydropyrochlore, (c) Nb-substituted hematite, (d) Nb-substituted goethite, (e) Nb-substituted

480 rutile, (f) Nb-substituted anatase, (g) Nb-substituted cerianite, (h) Nb perovskite with three pseudo-

481 Voigts (PV1, PV2, PV3) and an error function (ERF). The experimental (Exp.) and the fitted data

482 (Fit.) correspond to the black and purple curves. All spectra are satisfactorily fitted using this

483 procedure ($\chi^2 < 0.5$), but the fits of Nb-substituted anatase and Nb perovskite spectra are of poorer

484 quality ($\chi^2 = 0.41$ and 0.39, respectively) due to the broadening of B$_3$ features (Figs. 2f and 2h). The

485 deconvolution of the other XANES spectra is shown in Supplemental Material (Supplemental Figs.

486 S4 and S5).

487   Figure 3: Comparison of experimental (black dashed lines) and simulated spectra (red lines)

488   obtained by crystal field multiplet (CFM) calculations of (a) Nb-substituted cerianite, (b) Nb-

489   substituted hematite, (c) hydropyrochlore, (d) Nb perovskite. The thin red lines indicate the position

490   and intensity of the electronic transitions when experimental and core-hole lifetime broadenings are

491   absent. The t_{2g} and e_g terms used in the single-particle approach are employed in a matter of clarity

492   but they correspond to the convolution of multi-electronic states.

493   Figure 4: Comparison of experimental (black dashed lines) and simulated spectra (red lines)

494   obtained by ligand-field multiplet (LFM) calculations of Nb-substituted hematite spectra.

495   Figure 5: Experimental spectra of Nb perovskite (black spectra) and theoretical spectra depicting

496   the influence of hydridization strength (V_{mix} parameter varying from 0.0 to 5.0 eV with a 0.25 eV

497   step) on the Nb $L_{2,3}$-edges spectral shapes. The arrows mark the low intensity features resulting

498   from charge-transfer effect. Charge-transfer parameters are 3.0, 6.0 and 4.0 eV for U_{dd}, U_{dc} and Δ,

499   respectively.

500   Figure 6: Dependence between the energy splitting (ΔE parameter) at the L_3-edge and the expected

501   average distance (R) between [6]Nb–O or between Fe–O, Ti–O, Ce–O in the case of Nb-substituted

502   reference materials. Experimental data are best fitted with a function proportional to R^{-3} ($\chi^2 = 0.17$),

503   rather than a function proportional to R^{-5} ($\chi^2 = 0.26$). Experimental data corresponding to Nb-

504   substituted Ti oxides deviate from both models. The error bars on ΔE correspond to the instrumental

505   resolution of 0.25 eV at the Nb $L_{2,3}$-edges.

Table 1

Table 1. Structural and chemical information on the selected Nb minerals. (i), (ii) and (iii) correspond to the three groups of Nb minerals described in the main text. Commercial Nb_2O_5 was also selected as a reference material. The cation–O distances are Nb–O except for Ti, Fe and Ce oxides which correspond to Ti–O, Fe–O and Ce–O distances. The site symmetry is that of Nb sites in Nb-bearing minerals and of Fe, Ti and Ce in Fe, Ti and Ce oxides, respectively. The distortion index is calculated as defined by Baur (1974). The references giving the structure of each compound can be found in the Supplemental Material.

Mineral (groups i,ii,iii)	Ideal formula	Structure	Coordination number	Site symmetry (Nb, Ti, Fe, Ce)	Average cation–O distances (Å)	Distortion index (%)	Location
Natural samples							
(i) Fluorcalciopyrochlore	$(Ca,Na)_2(Nb,Ti)_2O_6F$	Corner-sharing NbO_6 octahedra sharing edges with A site cation	6	D_{3d}	1.944	0.0	Tatarka. Russia (SU)
(i) Hydropyrochlore	$(H_2O, \square)Nb_2(O.OH)_6(H_2O)$	Corner-sharing NbO_6 octahedra sharing edges with A site cation	6	D_{3d}	1.972	0.0	Lueshe. Congo (SU)
(i) Columbite-(Mn)	$(Mn,Fe)(Nb,Ta)_2O_6$	Chains of edge-sharing NbO_6 octahedra	6	C_1	2.017	6.0	Musha. Rwanda (ENSMP)
(ii) Niobian perovskite	$CaTi_{1-2x}Fe_xNb_xO_3$	Perovskite structure (ABO_3) with interconnected NbO_6 octahedra with interstitial Ca	6	C_1	1.966	0.6	Oka. Canada (ENSMP)
(ii) Niocalite	$Ca_7Nb(Si_4O_{14})O_3F$	Isolated NbO_6 octahedra sharing edges and corners with CaO_6 octahedra	6	C_1	2.049	6.1	Oka. Canada (ENSMP)
Synthetic samples							
(ii) Lueshite	$NaNbO_3$	Perovskite structure (ABO_3) with interconnected NbO_6 octahedra with interstitial Na	6	C_1	1.990	2.8	
(iii) Rutile (5 wt% Nb)	TiO_2	Edge and corner-sharing TiO_6 octahedra (2 edges are shared with each other)	6	D_{2h}	1.956	0.6	
(iii) Anatase (5 wt% Nb)	TiO_2	Edge-sharing TiO_6 octahedra (4 edges are shared with each other)	6	D_{2d}	1.949	1.0	
(iii) Hematite (1 wt% Nb)	$\alpha\text{-}Fe_2O_3$	Face and edge-sharing FeO_6 octahedra	6	C_3	2.031	4.2	
(iii) Goethite (1 wt% Nb)	$\alpha\text{-}FeOOH$	Chains of edge-sharing FeO_6 octahedra joined by corner-sharing FeO_6	6	C_s	2.026	3.8	
(iii) Cerianite (1 wt% Nb)	CeO_2	Edge-sharing CeO_8 cubes	8	O_h	2.343	0.0	
Nb_2O_5	Nb_2O_5	Edge and corner-sharing NbO_6 octahedra. 1 out of 28 Nb sites is a tetrahedron	6	C_1	2.014	1.5	

Table 2

Table 2. Summary of the parameters obtained from the fitting procedure including the energy splitting between the features A and B (ΔE), the relative intensity ratios (I_A/I_B) and the ratio of the B feature width with respect to A feature ($FWHM_{B/A}$). The quality of the fit is assessed using the Pearson chi-squared test (χ^2). The amplitude, center, width and intensity of the pseudo-Voigts can be found in Supplemental Table S3.

Sample	L_3-edge				L_2-edge			
	ΔE (eV)	I_A/I_B	$FWHM_{B/A}$	χ^2	ΔE (eV)	I_A/I_B	$FWHM_{B/A}$	χ^2
Nb cerianite	2.55	0.75	1.47	0.06	2.29	0.96	1.73	0.06
Nb_2O_5	3.28	0.94	1.73	0.04	3.06	1.24	1.92	0.04
Fluorcalciopyrochlore	3.90	1.18	1.48	0.09	3.83	1.55	1.69	0.06
Hydropyrochlore	3.76	1.07	1.62	0.05	3.64	1.41	1.67	0.04
Columbite	3.41	1.11	1.48	0.06	3.32	1.47	1.73	0.06
Niocalite	3.43	1.17	1.38	0.11	3.44	1.55	1.63	0.10
Lueshite	3.54	1.05	1.68	0.08	3.75	1.42	1.28	0.09
Nb perovskite	3.96	1.20	2.08	0.39	3.95	1.60	2.35	0.16
Nb hematite	3.44	1.08	1.12	0.28	3.47	1.45	1.39	0.10
Nb goethite	3.46	1.08	1.18	0.25	3.48	1.46	1.47	0.11
Nb anatase 1% Nb	3.38	1.10	1.58	0.51	3.30	1.48	1.84	0.19
Nb anatase 5% Nb	3.34	1.14	1.62	0.41	3.29	1.55	1.88	0.17
Nb anatase 10% Nb	3.33	1.14	1.61	0.39	3.28	1.55	1.92	0.15
Nb rutile 5% Nb	3.45	1.03	1.54	0.21	3.31	1.25	1.78	0.09

Table 3

Table 3. Crystal-field multiplet (CFM) parameters that best
reproduce the experimental spectra.

Sample	Nb point group symmetry	Slater integrals reduction	$10Dq$ (eV)
Nb-substituted cerianite	O_h	0.51	2.80
Nb-substituted hematite	O_h	0.51	3.70
Hydropyrochlore	O_h	0.54	3.90
Nb perovskite	O_h	0.35	3.90

Table 4

Table 4. Crystal-field and charge-transfer parameters that best reproduce the experimental spectra.

Sample	Nb point group symmetry	Slater integrals reduction	$10Dq$ (eV)	U_{dd} (eV)	U_{dc} (eV)	Δ (eV)	V_{eg} (eV)	V_{t2g} (eV)
